RELEASING factors¹ and other brain peptides² have been the subject of extensive studies and the high sensitivity of modern measurement techniques has led to the discovery, in various tissues^{3,4} and in the nervous system⁵⁻⁸, of new, unpredicted locations for otherwise well known peptides. Evidence for the presence in the vertebrate nervous system of a hitherto undescribed brain gastrin immunoassayable peptide (BGP) is presented here.

Various tissues and regions of the central nervous system (CNS) were studied using human material obtained 24 h after death and animal material was dissected immediately after decapitation. All specimens were inspected under the microscope for normality. For extraction of immunoassayable material, a 10% w/v suspension of fresh tissue in a buffer of potassium phosphate (0.05 M) and sodium chloride (0.15 M) at pH 7.4 was homogenised at 4°C with a glass homogeniser and a motor-driven Teflon pestle. Samples (2 ml) of homogenate were used for dry weight analysis and the rest was boiled for 15 min and then centrifuged at 100,000g for 30 min. Samples of supernatant were taken for estimation of Lowry-positive material¹⁰ and of gastrin immunoassayable material using a technique with antigastrin antibodies of high specificity¹¹. Limits of detection were 15 or 60 pg Gastrin 2-17 (hexadecapeptide, ICI) per ml in 200-μl or 50-μl samples, respectively.

To obtain a dose-response curve, Gastrin 2-17 and boiled extract of human cortical grey matter concentrated after lyophilisation were used. For standard curve establishment, Gastrin 2-17 was diluted in a buffer of potassium phosphate (0.01 M) and sodium chloride (0.15 M) at pH 7.4 containing 10 mg per ml egg albumin (Sigma), or in human cortical grey matter boiled extract from which immunoreactivity had or had not been removed by charcoal absorption¹².

Our results for gastrin in blood serum are in agreement with those published¹³⁻¹⁵ and similar results were obtained for

gastric antrum^{16,17}, obtained from autopsy material. Distribution of BGP is otherwise restricted to the nervous system (Table 1). Highest concentrations are found in cortical grey matter of all cerebral lobes; concentration in the hypothalamus is much lower and similar to concentrations of brain stem and spinal cord. BGP was not detectable, in the peripheral nervous system, in cerebellum nor in any invertebrate nervous system studied so far (Table 2).

Dose-response curves (Fig. 1) with unlabelled Gastrin 2-17 are different from those obtained with successive dilutions of concentrated boiled cortical grey matter extract. When Gastrin 2-17 is diluted in boiled brain extract from which immunoreactivity has been removed by charcoal absorption¹² the dose-response curve is very similar to that obtained with regular diluant. When Gastrin 2-17 is added to immunoreactive boiled brain extract, a further decrease in the bound-to-free radioactivity ratio was obtained. On the contrary, however, the slope of the dose-response curve is less accentuated with concentrated boiled cortical grey matter extract, than with Gastrin 2-17, and with the highest concentrations the bound-to-free ratio rests near 0.10. These differences in dose-response curves were observed with two different rabbit antigastrin sera.

Following Feldman and Rodbard¹⁸, we can use the equation

$$R^2 + R(P'K + PK - QK + 1) - QK = 0 \quad (1)$$

(*R* is the bound-to-free ratio, *P'* the concentration of labelled Gastrin 2-17, *P* the concentration of unlabelled Gastrin 2-17, *Q* the concentration of antigastric antibodies sites, and *K* the antibody affinity constant at equilibrium for Gastrin 2-17) to calculate from the dose-response curve an affinity constant for Gastrin 2-17 of our antibody of 4.9×10^{10} l per mol Gastrin 2-17. This figure is similar to the values obtained by Rehfeld *et al.*¹⁸ which are between 0.5×10^{10} and 100×10^{10} l mol⁻¹ Gastrin 2-17. Similar calculations with BGP dose-response curve lead to an affinity constant of 0.9×10^{10} l mol⁻¹, showing clearly that BGP and Gastrin 2-17 are not identical competitors ($K_{\text{gastrin}} = 5.4 \times K_{\text{BGP}}$) with labelled Gastrin 2-17 for binding our antigastrin antibody. Whether these differences in affinity and the plateau obtained with highest concentrations of BGP are a result of the presence of different antigastrin antibodies at different concentrations, some reacting with Gastrin 2-17 and BGP, some reacting only with Gastrin 2-17, remain to be studied.

Disappearance of immunoreactivity of BGP, gastric antrum extract and Gastrin 2-17 was obtained with incubation at 37°C and pH 7.4 for 30 min with Pronase E (70,000 PUK g⁻¹, Merck) 1 mg ml⁻¹ or chymotrypsin A₄ (für analytische Zwecke, Boehringer) 1 mg ml⁻¹. With 1 mg ml⁻¹ trypsin (für analytische Zwecke, Boehringer), 70% of the immunoreactivity was preserved, as with gastric antrum extract or Gastrin 2-17. This is in accordance with the relative resistance to trypsin of Gastrin

Table 1 Distribution of gastrin immunoassayable substance in selected human tissues

Tissue	Dry weight	Lowry-positive material	Gastrin assay
Cerebral lobes	344 ± 3	21 ± 0.3	130 ± 7
Gastric antrum	302 ± 6	36 ± 1.3	14,800 ± 700

Tissue dry weight in mg per g wet weight, boiled extract gastrin immunoassayable material in ng per g dry weight. Means and standard errors of the mean (\pm s.e.m.) for three separate (three autopsies or three animals) determinations are presented. Appropriate dilutions to perform gastrin radioimmunoassay (gastrin assay) on samples with immunoreactivity below 80 pg gastrin per 50- μ l or 200- μ l sample.

* ng per g net weight.

2-17 previously reported²⁰. Disappearance of immunoreactivity of BGP after action of proteolytic enzymes, resistance of BGP to boiling for 15 min at 100 °C and its absorption on charcoal favour a small peptide molecule. Preliminary results with Sephadex G25 (columns 2.8 cm in diameter and 45 cm long) show that BGP is eluted between Gastrin 2-17 and ¹³¹I. This sets the molecular weight of BGP to less than that of Gastrin 2-17 (2,020).

BGP is different from releasing factors in that its highest concentration is found in the cortex. Of other natural substances related to gastrin by amino acid composition, cholecystokinin-pancreozymin and caerulein²¹, none has been described previously in cortical grey matter. The discovery in the vertebrate CNS of a new peptide reacting with gastrin antibodies is not unexpected in view of the postulated neural crest origin of the endocrine polypeptide (APUD) cells of the

gastrointestinal tract and pancreas²². The interest in brain-restricted peptides is that they are likely candidates for involvement in the function of the nervous system. At a time when the brain is increasingly being considered not only as a tissue with synaptic connections but also as an "endocrine organ and hormone target"²³, such a new peptide takes on an even greater significance.

Role of sodium in neuronal uptake of monoamines and amino acid precursors

It is generally accepted that the neuronal re-uptake of monoaminergic neurotransmitters after their release into the synaptic cleft, inactivates transmitter action^{1,2}. The amino acid precursors L-tyrosine and L-tryptophan are also taken up by neurones from the circulation³⁻⁵. Using *in vitro* models of these processes, it has been demonstrated that tricyclic antidepressant drugs inhibit the uptake of both the amines^{6,7} and their precursors⁸ into synaptosomal fractions obtained from rat brain homogenates. Amino acids can be transported into cells by an Na⁺-dependent, Na⁺-independent or an Na⁺-inhibited transport system⁹. Monoamines, however, have been reported^{10,11} to have only an Na⁺-dependent system. Since information is lacking concerning the uptake of L-tyrosine and L-tryptophan, we have attempted to determine the role of Na⁺ ions in the uptake of the amino acid precursors compared with that of monoamines.

The uptake of the amino acids ¹⁴C-L-tyrosine and ¹⁴C-L-tryptophan and their related monoamines ¹⁴C-1-noradrenaline (NA), ¹⁴C-dopamine (DA) and ¹⁴C-5-hydroxytryptamine (5-HT) was studied in a crude synaptosomal fraction obtained from rat brain homogenate. The preparation of synaptosomal fractions and the methods used for the uptake experiments have been described⁸ (see legend to Fig. 1 for details). After incubation of the amino acids the pellet did not contain measurable amounts of formed monoamines (unpublished results and ref. 12). No attempt was made to separate the ¹⁴C-monoamines from metabolites formed, but, to prevent degradation of the monoamines by monoamine oxidase (MAO) an MAO-inhibitor (nialamide) was added to the incubation fluid⁶. The samples were centrifuged after incubation for 30 min at 70,000g, the supernatant discarded and the pellet rinsed twice with cold buffer. The pellet was dissolved in 1.0 ml deionised water by ultrasonic disintegration (5 s) and then 12 ml Instagel was added. Radioactivity was measured with a Packard liquid scintillation spectrometer.

Figure 1 shows the uptake of both amino acids by synaptosomes incubated in Krebs-phosphate buffer containing different Na⁺ concentrations and it can be seen that replacement of Na⁺ by sucrose resulted in an increased uptake. Thus, increasing the Na⁺ concentration inhibits the uptake of amino acid, but the uptake of the three monoamines studied is enhanced when the Na⁺ concentration is increased (Fig. 1b). Although it is known that the uptake of NA and 5-HT is Na⁺-dependent^{10,11}, a small amount is taken up in the absence of Na⁺. An effect of sucrose on the uptake processes seems rather unlikely since replacement by sodium by choline produced the same effects as replacement by sucrose (unpublished). Our results show that uptake of 5-HT was maximal at 50 mM Na⁺, whereas the uptake of NA and DA was maximal at about 100 mM Na⁺. *In vitro* conditions can, therefore, be created in which the uptake of 5-HT will be nearly maximal (25 mM Na⁺) without affecting the uptake of NA or DA. Optimal conditions for the uptake of NA, DA and 5-HT differ considerably from those for tyrosine and tryptophan.

Transformation of these results into a physiological model suggests that the re-uptake of monoamines and the uptake of amino acid precursors into nerve terminals is regulated by cation fluxes which are also responsible for the generation and conduction of impulses. During depolarisation, Na⁺ influx is increased and so an Na⁺ deficiency near the extracellular site of the axonal membrane may ensue. This Na⁺ deficiency will promote the uptake of tyrosine into the nerve ending, while at the same time NA or DA will be released into the synaptic cleft as a consequence of an increased influx of Ca²⁺ ions during depolarisation¹³⁻¹⁵. Both the increased intraneuronal tyrosine concentration and the release of NA

Fig. 1 *a*, Effect of Na⁺ concentration on the uptake of L-¹⁴C-tyrosine and L-¹⁴C-tryptophan by a synaptosomal fraction *in vitro*. The synaptosomal fraction was suspended in a Krebs-phosphate buffer (pH 7.4) (5 ml per g of tissue) containing (in mM): NaCl 118.46; KCl, 4.74; CaCl₂, 1.27; KH₂PO₄, 1.18; MgSO₄, 1.18; Tris-HCl, 16.15 and 40.0. For each incubation experiment 0.5 ml of the suspension, equivalent to a synaptosomal fraction from 100 mg of brain tissue, was used. Synaptosomes were preincubated for 15 min at 37 °C in a shaking incubator, and the ¹⁴C-labelled compound, dissolved in 0.5 ml Krebs buffer, was added and incubation continued for a further 5 min. Incubation was stopped by placing the incubation vessels in ice water. Buffers containing different Na⁺ concentrations were prepared by replacing NaCl isosmotically by sucrose. Uptake was measured 5 min after addition of L-¹⁴C-tyrosine (2×10^{-6} M; 3.4 mCi mmol⁻¹) or L-¹⁴C-tryptophan (0.25×10^{-6} M; 13.9 mCi mmol⁻¹). Quenching was measured by the automatic external standardisation (AES) ratio method. *b*, Effect of Na⁺ concentration on uptake of NA, DA and 5-HT by a synaptosomal fraction *in vitro*. Conditions were as described in *a* except that the incubation fluid also contained nialamide (10^{-4} M). Uptake was measured at bath concentrations of 5×10^{-6} M. Specific activities: NA, 54 mCi mmol⁻¹; DA, 57.3 mCi mmol⁻¹; 5-HT, 54 mCi mmol⁻¹. Compounds used and specific activities: L-tryptophan (methylene-¹⁴C), 52 mCi mmol⁻¹; L-tyrosine-¹⁴C (U), 522 mCi mmol⁻¹; 5-HT-3'-¹⁴C creatinine sulphate, 55 mCi mmol⁻¹; dopamine (ethylamine-2-¹⁴C) hydrochloride, 57 mCi mmol⁻¹; 1-noradrenaline *d*-bitartrate (methylene-¹⁴C), 57 mCi mmol⁻¹ (all Radiochemical Centre, Amersham). *a*, ●, L-tyrosine; ○, L-tryptophan; *b*, ●, NA; ▲, DA; ■, 5-HT.

or DA will enhance biosynthesis of these transmitters, because more precursor is now available and the product feedback repression of tyrosine hydroxylase is removed¹⁶⁻¹⁸. Furthermore, the biosynthesis of NA or DA may be increased by the influx of both cations which have been reported to activate tyrosine hydroxylase^{18,20}.

During the restoration phase Na⁺ ions are expelled into the extracellular space which induces re-uptake of monoamines. During the resting state the uptake of monoamines is thus optimal, while the synthesis and release of monoamines is inhibited. During depolarisation, however, the release and synthesis of monoamines is activated and at the same time the re-uptake of tyrosine and tryptophan is enhanced. During this phase of the action potential the re-uptake of monoamines is inhibited. This impairment of the uptake of monoamines, after their release into the synaptic cleft, potentiates the action of the released transmitter on its receptor. The same mechanism for a coupling between impulse inflow or cation fluxes and release, synthesis and re-uptake of transmitter can be applied to 5-hydroxytryptaminergic nerves, but in this case the uptake of tryptophan may be more critical for an increased biosynthesis of 5-HT since as yet no product feedback repression of tryptophan hydroxylase is known.

Since the most important assumption of this hypothesis is the extracellular deficiency of Na⁺ ions near the axonal membrane during depolarisation, a theoretical calculation concerning this problem is given below. If one assumes that the area of the presynaptic membrane is 1 μm^2 and the extracellular Na⁺ ion concentration is 0.1 M, the number of Na⁺ ions per μm^3 will be $10^{-16} \times 0.1 \times \text{Avogadro's number } (N)$. N is 6×10^{23} , so the number of Na⁺ ions per μm^3 will be 6×10^7 . Assuming a uniform distribution of Na⁺ ions, the number of Na⁺ ions occupying 1 μm^2 will be $(6 \times 10^7)^{2/3} = 15 \times 10^4$ Na⁺ ions. In non-myelinated nerve tissue each impulse will cause an influx of 20,000 Na⁺ ions per μm^2 (ref. 19), so deficiency near the axonal membrane might occur if the diffusion of extracellular Na⁺ is slow enough.

In cases of frequent stimulation, it is not unlikely that after seven impulses a complete layer of Na⁺ ions will have disappeared. In the synaptic cleft, which has a volume of about 0.02 μm^3 , only eight layers of Na⁺ ions are present, each consisting of 150,000 Na⁺ ions. These ions not only serve to conduct the presynaptic action potential, but may also be needed for the generation of a postsynaptic action potential. Although no data are available of the diffusion of Na⁺, or other ions, near the axonal membrane or in the synaptic cleft, one might expect that in a supercapillary system such as the synaptic cleft, the pre- and postsynaptic resting potential would exert a strong influence on the displacement of ions. The negative resting potentials at the pre- and postsynaptic

site will fix the position of Na⁺ ions in the synaptic cleft. During depolarisation of the presynaptic membrane, 20,000 Na⁺ ions will enter the presynaptic nerve ending, resulting in a decrease of the negative potential. Therefore, during depolarisation, the remaining Na⁺ ions present in the synaptic cleft will shift to the postsynaptic site, creating an Na⁺ deficiency near the surface of the presynaptic membrane. Thus, supposing that during depolarisation the displacement of extracellular Na⁺ ions is sufficiently slow, an Na⁺ deficiency near the axonal membrane might be expected. This condition will be favourable for an increased uptake of amino acid precursors simultaneously with an inhibition of the re-uptake of the stimulus-induced released monoamines. During the restoration phase, when the efflux of Na⁺ ions is increased, the re-uptake of monoamines is restored, and the biosynthesis will slow down as a result of product feedback repression and (or) an impairment of the uptake of amino acid precursor (Fig. 2). In this way synthesis, release and re-uptake of monoaminergic neurotransmitters are all coupled to cation fluxes which occur during nervous impulse flow.

Na⁺ and Ca²⁺ ions

Enteropancreatic circulation of digestive enzyme as a conservation mechanism

THE permeability of the intestine to pancreatic digestive enzymes has been known for some years¹⁻⁷. Recently it was demonstrated⁸ that chymotrypsinogen and amylase are transported across the pancreatic acinar cell as well. Taken together these observations suggest that some of the digestive enzymes which are secreted into the intestinal lumen are circulated by way of the bloodstream and acinar cell back into the intestine. This prediction was borne out experimentally. ³H-chymotrypsinogen instilled into the intestinal lumen reappeared in pancreatic secretion within minutes⁸. The question remained, however, whether this "enteropancreatic circulation" was a trace process either of a trivial nature or serving a regulatory function; or, whether—analogueous to the enterohepatic circulation of bile salts—it was a process in which substantial amounts of digestive enzyme could be circulated and thereby conserved. The

Fig. 1 Pancreatic protein secretion with time. After 30 min (arrow) pancreatic secretion was continuously stimulated with secretin (1 U per kg body weight, intravenously) and acetyl- β -methylcholine chloride (0.5 mg per kg body weight, subcutaneously) by injections every 30 min. Pancreatic juice was either diverted (and replaced by an equal quantity of albumin) (open bars), instilled into the duodenum (stippled bars), or injected intravenously (hatched bars). In these conditions, enzyme secretion declined in a roughly exponential manner when the digestive enzyme was diverted (control). When enzyme was added back to the system, either by intravenous injection or intestinal instillation, this fall-off was less pronounced. Error bars indicate the s.e.m. The number of experiments is given at the bottom of each bar. Statistical analysis was done using the Mann-Whitney test for periods between 90 and 150 min and Student's *t*-test for periods thereafter. For statistical analysis the protein output of each period was normalised for the peak response (60 min) to control for inhomogeneity of variance between experiments. **P* < 0.05; †*P* < 0.025; ‡*P* < 0.01.

experiments reported here are consistent with this latter view and suggest the circulation of approximately 60% of a mixture of digestive enzymes instilled into the duodenum (82–92% at steady state).

The pancreatic duct of male white New Zealand rabbits weighing 2–3 kg was cannulated *in situ* after a median laparotomy under DIAL-urethane anaesthesia (0.7 ml per kg body weight intraperitoneally) and subsequent to a 20 h fast. The continuity of the gastrointestinal lumen was maintained. Protein content was estimated by ultraviolet absorption at 280 nm. These measurements were comparable with values obtained with the Folin phenol reagent (protein content was estimated using both methods in selected experiments)⁹. After a 30-min unstimulated collection period, maximal secretion of both protein and fluid was continuously elicited by half-hourly injections of acetyl- β -methylcholine chloride (0.5 mg per kg body weight subcutaneously) and porcine secretin (1 Ivy dog unit per kg body weight intravenously) (kindly provided by Professor V. Mutt of the Karolinska Institutet). Samples were collected at 30-min intervals.

When pancreatic juice was completely diverted from the intestine, a roughly exponential decay in protein secretion was seen. In the continued presence of the cholinergic stimulus, secretion decreased by about 90% over a 4.5-h period (Fig. 1), although it was still enhanced relative to the secretion of protein from unstimulated glands at the same time (4.5 h).

While this decay or fall-off in protein secretion might have resulted solely from fatigue in the system, for example

decreased responsiveness to the stimulus or energy limitations relative to transport, it might also have been due to the diversion of digestive enzyme itself, which would remove the supply of available enzyme from a presumptive enteropancreatic circulation. To distinguish between these two possibilities, we collected pancreatic digestive enzyme secretion, stimulated as described above, measured its protein content, and immediately reintroduced it into the duodenum (without any modification of the material), thereby maintaining the continuity of the natural process. Under these conditions the fall-off was indeed less than during diversion (Fig. 1) (log protein output against time for the data in Figure 1; $b_{\text{diverted}} = -0.004$ ($r = 0.97$), $b_{\text{instilled}} = -0.0028$ ($r = 0.94$); b_{div} against b_{inst} , $P < 0.025$). A relatively steady protein output was maintained under these conditions for about 3 h, although not at maximal rates. The increase in protein secretion after protein instillation into the intestinal lumen was equal to 61.3 ± 10.6 s.e.m. ($n = 6$) of the amount instilled for the complete experiment (relative to time-paired controls (diverted)), and reached a maximum of 83% for the period of peak response (Table 1). This increase in pancreatic protein output might have come about indirectly from the release of hormones into the blood after the instillation of pancreatic juice into the intestine as well as from the direct circulation of enzyme molecules. To test for this possibility, at least for the hormone known to produce substantial changes in total protein output by this gland, cholecystokinin-pancreozymin (CCK-PZ), an experiment was done in which pancreatic juice was again completely diverted, but at 120 min 1 Ivy

Table 1 Circulation of pancreatic enzymes under steady-state conditions

Condition	<i>a</i> Protein input at 210 min	<i>b</i> Protein output 210–240 min	<i>c</i> Control output 210–240 min	<i>b</i> – <i>c</i>	Percentage recirculated, [(<i>b</i> – <i>c</i>)/ <i>a</i>] × 100
Intestinal instillation	3.1	4.1	1.5	2.6	83%
Intravenous injection	3.6	4.4	1.5	2.9	80%

dog unit of purified CCK-PZ per kg body weight was injected in addition to the other stimulants (as in Fig. 1) for the remainder of the experiment. No significant additional augmentation of protein secretion was seen under these conditions.

By contrast, if the circulation of intact digestive enzyme did indeed account for the increased protein output, then the intravenous injection of pancreatic juice should produce a similar response to that seen after intestinal instillation. This was observed (Fig. 1). There was an increase in protein secretion relative to controls equal to $51.6\% \pm 5.5$ s.e.m. of the protein injected during the course of the complete experiment with a maximum of 80.2% for the period of peak response (Table 1) (log protein output against time for the data in Fig. 1; $b_{\text{injected}} = -0.0022$ ($r = 0.94$); b_{div} against b_{inj} , $P < 0.001$).

The relationship between the amount of digestive enzyme instilled or injected and increased enzyme secretion as a result of either can be more clearly evaluated by plotting the response as a function of the amount of digestive enzyme instilled or injected in individual experiments. This is true because the amount of enzyme applied varied considerably from experiment to experiment. When the data were treated in this manner, the variance virtually disappeared and the response was proportional in a roughly linear fashion to input ($y = 0.92x + 3.75$, $r = 0.97$). The calculated slope was now 0.92 or the equivalent of 92% circulation. The difference between the overall responses (61% for instillation and 52% for injection) and the slope for the data as presented in Fig. 2 is found in the positive x-intercept ($x = 19.7$), which represents the amount of enzyme that must be added to the system before there is a response. This is the system 'capacitance' and may include various enzyme-containing compartments, such as the intestinal lumen, absorptive cells, blood, kidney, and of course the pancreas itself. Apparently, the size of the capacitance is roughly the same regardless of how the enzyme is administered since both injected and instilled experiments regressed similarly with approximately equal intercepts ($x_{\text{inst}} = 18$, $x_{\text{inj}} = 21.5$). The fact that one point was negative suggests that our function as calculated is slightly

displaced. If we correct this by setting the difference between control and experimental values equal to zero for the lowest response (the negative point) and adjust the other experimental points equivalently, the positive intercept of the x-axis is still substantial (uncorrected x-intercept = 19.7, corrected x-intercept = 13.5) and significantly different from 0 ($P < 0.001$).

While circulation of digestive enzyme is the most direct interpretation of these data, particularly since the potential for such a process has been demonstrated⁸ and also because input and output are almost equivalent at the steady state, the injected or instilled enzyme could still have produced the effect in other ways such as by the release of as yet undescribed secretagogues or by regulating enzyme secretion directly at the acinar cell level. If indeed the enzyme is being circulated, then, at least for the situation of maximally stimulated secretion in the absence of food, the efficiency of the process is remarkably high, of the order of 80–90%.

The conservation of digestive enzyme by its circulation could provide for a substantial saving of energy for digestion, that is, it would eliminate at least in part the need to metabolically recycle digestive enzyme by the liberation (protein breakdown), absorption, and reincorporation of amino acids into new protein.

Fig. 2 The relationship between enzyme input (intestinal instillation (●) or intravenous injection (×)) and the circulation of digestive enzyme in each individual experiment (the difference between total protein output in each experiment ($\Sigma_{1 \rightarrow n}^{\text{Expt}}$) and the average total output for control experiments for the same duration ($\bar{X}_{1 \rightarrow n}^{\text{Control}}$). The amount of enzyme circulated varied directly and linearly with the amount of enzyme added to the system with a slope of 0.92 or 92% of the input being circulated. The positive x-intercept represents the input capacitance of the system.

Increased breakdown of glycosaminoglycans and appearance of corrective enzyme after skin transplants in Hunter syndrome

ATTEMPTS to treat the mucopolysaccharidoses with infusions of normal plasma or leukocytes have produced mixed results; some workers^{1–3} reported little or no positive effect, while others^{4–6} noted both clinical and biochemical changes after treatment. Among the more obvious reasons for these conflicting findings are differences in the responsiveness to treatment of genetically distinct forms of the disorders⁷, in the volumes of plasma administered and in the activities of the corrective factors in the plasma.

Replacement therapy by infusion of plasma can at best provide only a temporary solution, since the half lives of the enzymes involved are of the order of a few days only^{8–10}. The changes we observed immediately after infusion^{6,7,11,12} were, however, sufficient to encourage an attempt to provide a more permanent source of corrective factors. Accordingly, skin allografts were transplanted on a 4-yr-old boy (B.G.) with Hunter syndrome, who, 11 months earlier, had shown a positive response to plasma infusion therapy¹². The diagnosis was established first on the typical clinical features, second on probable X-linked inheritance, since the mother had another affected son by an earlier marriage and third, by cultured fibroblast correction experiments using typed reference cells. Both the mother (HL-A:

Fig. 1 Total 24-h excretion of urinary uronic acid before and after skin grafting. The day of grafting is designated day 0, and the days before grafting by negative numbers. Stippled areas of columns, polymeric uronic acid; open areas of columns, uronic acid fragments

W32,9,12,y) and the father (HL-A:1,2,8,17) had two HL-A antigens in common and two incompatible with the patient (HL-A: 1,9,8,y) (y indicates an unidentified antigen of the second series). In the mixed leukocyte reaction the patient's cells had no reaction when mixed with maternal cells but showed an approximate threefold increase in incorporated radioactivity when mixed with paternal leukocytes. But the patient received skin allografts from both parents, because it was reasoned that the dose of genes responsible for the Hunter corrective factor might be higher in skin cells derived from the father than from the mother (who was an obligatory heterozygote in whom an unknown proportion of wild genes on Lyonised X chromosomes might be inactive).

Full thickness elliptical skin 5 cm × 2 cm was taken from the inner side of the left upper arm of the mother and father, and grafted on the flexor aspect of the forearm of the child. Immunosuppressive treatment (azathioprine, 25 mg daily, prednisolone, 25 mg twice daily), was commenced 7 d before grafting and continued (at the same doses for 6 weeks and then on progressively smaller doses) for 9 months.

Initially both grafts were judged to have taken and were pink after 2 weeks. Four weeks after transplant the paternal graft was rejected. Six weeks after transplant it was judged that about 90% of the maternal graft had taken, but this too was rejected about 3 months after transplantation.

Urine collections (24 h) taken before and after grafting were stored at -20 °C with 10 ml of toluene until analysed. Polymeric glycosaminoglycans (GAG) were isolated from 200-ml samples by precipitation with 9-aminoacridine HCl and conversion to their sodium salts^{13,14} and the GAG fragments that remained in the supernatant solution were collected on a column of Dowex-1 × 2 (ref. 4) and eluted with 2 M sodium chloride. Both fractions were assayed for their uronic acid contents¹⁵. The GAG fragments eluted from Dowex were concentrated by positive pressure dialysis through a filter membrane (UM-05, Amicon) and 1-ml samples containing approximately 1 mg of uronic acid were chromatographed on a column (13 mm × 600 mm) of Sephadex G-25 'fine'. The relative proportions of high and low molecular weight fractions I and II respectively (Fig. 2) were determined by tracing the elution profiles on to thin paper, then cutting out and weighing the area under

each peak. Sulphate-uronic acid ratios were determined as before¹¹.

Crude Hunter corrective factor was isolated from urine samples using part of the method described by Cantz *et al.*⁸. The precipitate from urine made 70% saturated with ammonium sulphate was redissolved in water, insoluble residue was discarded after centrifugation, and the supernatant solution was made 50% saturated with ammonium sulphate. The resulting precipitate was removed by centrifugation and the supernatant solution was made 80% saturated. This last precipitate was again dissolved in water, freeze-dried and stored at -15 °C. Weighed amounts were redissolved in 1 ml of 0.01 M phosphate buffer, pH 6.0, in 0.15 M NaCl, dialysed against three changes of the same buffer (500 ml) at 2 °C for 20 h, then assayed for corrective activity⁸ using cultured fibroblasts from the patient.

Some 25–30% of the patient's total 24-h uronic acid was excreted as polymeric GAG before grafting (Fig. 1). After treatment the proportion of polymeric GAG decreased considerably, varying between 15 and 20% while at the same time total uronic acid excretion increased markedly, reaching a peak almost three times higher than pretreatment levels, on the 35th day after grafting. At this time polymeric GAG accounted for less than 10% of the total.

The GAG fragments eluted from Dowex were separated

Table 1 Changes in the size distribution and sulphate-uronic acid ratio of uronic acid oligosaccharides eluted from Sephadex G-25 before and after skin grafts

Day of treatment	Percentage of total uronic acid eluted		Sulphate-uronic acid ratio of Fraction II
	Fraction I	Fraction II	
- 12	48	52	1.7
- 9	48	52	—
- 5	56	44	—
+ 5	33	67	2.1
+ 11	40	60	—
+ 15	33	67	—
+ 33	26	74	—
+ 235	31	69	1.1
+ 296	16	84	1.2
+ 422	14	86	0.5

Fractions I and II are the high and low molecular weight components respectively shown in Fig. 2.

into three components by chromatography on Sephadex G-25 (Fig. 2), of which the largest was eluted closely behind the void volume followed by an oligosaccharide component of smaller molecular size and finally a tail fraction. Before treatment, the largest of these components contained approximately half the total uronic acid eluted from the column (Table 1), but by the fifth day after grafting this had decreased to one third of the total and the proportion continued to decrease with time, amounting to 26% by day 33 and 14% by day 422. Coupled with the increase in relative proportions of component II was a decrease in the ratio of SO_4 :uronic acid of this fraction from values near 2.0:1 down to only 0.5:1, 422 d after grafting.

Three normal children aged 4.5–8 yr excreted 89.2–104.7 U of Hunter corrective factor in their urine every 24 h. (1 U was defined by Cantz *et al.*⁸ as sufficient to induce half maximal correction of sulphate incorporation.) In contrast, the patient 270 d before skin transplant (and 42 d after receiving 1,600 ml of plasma from normal blood)

Fig. 2 Sephadex G-25 gel filtration profiles of uronic acid fragments eluted from Dowex-1. Samples containing 1 mg of uronic acid were eluted from the column in 0.2 M sodium acetate, pH 6.8. Fractions (0.85 ml) were collected and their uronic acid contents determined by an automated procedure. The dotted line indicates the boundary between fractions I and II (see Table 1). Sephadex filtration analysis was carried out on each of the six preoperative samples represented in Fig. 1. The two which are shown were selected because they show the extremes of preoperative variation. Thus the profile on day -9 had the greatest oligosaccharide component of any of the preoperative samples.

Table 2 24 h Urinary excretion of Hunter corrective factor

Source of urine	*Units of correction excreted per 24 h
Female control, age 4 yr 6 months	89.2
Male control, age 8 yr	104.7
Male control, age 4 yr 6 months	95.2
Patient, day -270†	0.86‡
Patient, day 15	0.00
Patient, day 54	0.12
Patient, day 98	3.62
Patient, day 237	4.89

*Units of correction were calculated from a dose-response curve constructed by plotting the degree of correction of the patient's fibroblasts (fall in radiol sulphate incorporation per mg of fibroblast protein) induced by serial dilutions of corrective factor⁸. Duplicate values agreed within $\pm 2.4\%$ except those for the female control which agreed to within $\pm 6.1\%$. Samples prepared from control urines and from the patient gave a mean corrective value of 0.34 units per 24 h after they had been boiled for 5 min. This control level was subtracted from all results obtained with unboiled preparations.

†Day 0 is defined as the day on which skin transplant was performed.

‡This urinary collection started 42 d after the patient had received an intravenous infusion of 1,600 ml of plasma from normal blood.

excreted only 0.86 U. As Table 2 shows, corrective factor excretion was low until 54 d after transplant but had risen significantly 98 and 237 d after transplant.

The large increase in excretion of uronic acid and in the relative proportions of oligosaccharides of low molecular weight, strongly suggest that in this patient, the grafts had released sufficient Hunter corrective factor to induce these changes. Since the defective enzyme in the Hunter syndrome is sulpho-L-iduronate sulphatase¹⁰, the increased desulphation of low molecular weight GAG further supports this view. We have reported similar evidence for GAG degradation after infusion of normal plasma^{6,7,11,12}, but on this occasion nonspecific effects attributable to an increase in blood volume after transfusion could be discounted; moreover the production of the Hunter corrective factor was confirmed by demonstrating its appearance in the urine.

The amount of corrective factor excreted increased during the period of observation, even though both grafts seemed clinically to have been rejected by day 100. It is possible, however, that some of the donor cells survived longer, since the amount of corrective factor excreted was still greatly in excess of pretreatment levels 237 d after grafting (Table 2), although its half life *in vitro* is only 2 d (ref. 8). Active concentration by fibroblasts of deficient enzymes has previously been demonstrated *in vitro* for other types of mucopolysaccharidosis^{9,10}. Thus, the delayed excretion of Hunter corrective factor observed in this case can be explained if all of the enzyme produced by the graft initially was taken up by the patient's cells. Alternatively the data are also consistent with the explanation that cells in the graft produced a factor which stimulated the patient's cells to produce corrective factor.

We thank Dr Brian H. Kirman for referring the patient to us, Miss Lesley Kennedy and Mr A. R. Jones for carrying out tissue typing and mixed leukocyte reactions, Miss A. A. Bazany and Mr S. Brown for technical assistance, and the Medical Research Council, the Arthritis and Rheumatism Council, The Wellcome Trust and the Spastic Society for financial support.

Approval for the transplants was obtained from the Guy's Hospital and Medical School Committee on Ethical Practice.

Human serum lyses RNA tumour viruses

ALTHOUGH there is agreement that oncornaviruses infect and are associated with malignancies in mice, cats and chickens¹, the evidence for oncornavirus infection in man remains controversial². Similarly, antibodies to oncornavirus antigens have been detected in laboratory animals³⁻⁷, but there are few data indicating the presence of such antibodies in humans^{8,9}. These findings suggest that man possesses a natural defence mechanism which inhibits or interferes with oncornavirus infection and replication. We report here evidence for such a mechanism.

Oncornaviruses isolated from several animal species were found to be inactivated by fresh human serum. As determined by an XC cell plaque reduction assay¹⁰, a 1:2 dilution of human serum inactivated 2.5×10^5 plaque-forming units (PFU) of Moloney leukaemia virus (MLV). The 50% end-point dilution for all of five human sera tested was approximately 1:16 for AKR leukaemia virus, Friend leukaemia virus, MLV, and Rauscher leukaemia virus (Table 1). Similarly, by using a focus reduction assay, a 1:16 dilution of human serum inactivated Moloney sarcoma virus (MSV), simian sarcoma virus, and MSV-gibbon ape leukaemia virus pseudotype. There was, however, no demonstrable inactivation of oncornaviruses by heated (56 °C, 30 min) human serum or by fresh sera from guinea pigs, rabbits, or mice (BALB/c and NIH Swiss). To determine the mechanisms of viral inactivation, SCRF 179 cells, an established murine lymphoid line free of mycoplasma and persistently infected with MLV (SCRF 179 (MLV)), were grown in medium con-

Fig. 1 Effect of human serum on sedimentation of MLV. MLV, labelled with ³H-uridine, was purified in sucrose gradients and, without a freeze-thaw, was reacted at 37 °C for 30 min with fresh human serum (●), heated (56 °C, 30 min) human serum (○), or 1% bovine serum albumin (△). The mixtures were layered on to 4.5 ml 20 to 50% (w/w) sucrose gradients in TES buffer (0.01 M Tris, pH 7.4; 0.05 M NaCl; 0.001 M EDTA). The gradients were centrifuged in a Spinco rotor SW 50.1 at 50,000 r.p.m. for 1 h and fractionated into 0.7-ml samples. Counts were made in Aquasol (New England Nuclear) using 20-μl samples.

taining ³H-uridine (15 μCi ml⁻¹; 40-50 Ci mmol⁻¹). Labelled MLV was purified, incubated for 30 min at 37 °C with bovine serum albumin (BSA), heated human serum or fresh human serum, and analysed by sucrose gradient ultracentrifugation. Figure 1 shows that after being incubated with either BSA or heated human serum the virus-associated radioactive counts sedimented to the lower portion of the gradient. This radioactivity was precipitable by 10% cold trichloroacetic acid (TCA) and resisted degradation by RNase (20 μg ml⁻¹). In contrast, when MLV was mixed with fresh human serum, most of the label remained at the top portion of the gradient and was not quantitatively precipitated by TCA. These results indicated that fresh human serum released RNA from the virus, presumably by lysis¹¹.

Fresh but not heated human serum released RNA-dependent DNA polymerase (RDDP) from six different oncornaviruses (Table 2) and such RDDP release could be

Table 1 Inactivation of oncornaviruses by human serum

Virus	Untreated	Plaque number after treatment:					With heated serum 1:2
		1:2	1:4	1:8	1:16	1:32	
AKR leukaemia virus	185	0	0	0	42	112	190
Friend leukaemia virus	206	0	0	0	48	127	210
Rauscher leukaemia virus	489	ND	0	14	69	370	498
Moloney leukaemia virus	880*	4	18	49	139	620	811

Equal volumes of virus and human serum (fresh or heated at 56 °C for 30 min) dilutions were incubated at 37 °C for 30 min. Duplicate 0.4-ml samples of the virus-serum mixtures were inoculated on to monolayers of secondary NIH Swiss mouse fibroblasts (24 h old) in the presence of polybrene (2 μg ml⁻¹). Cultures were refed 1 and 4 d after infection, irradiated with ultraviolet light, and overlaid with 10⁶ XC cells per Petri dish¹⁰. These cells were refed 1 d and fixed and stained 3 d after irradiation.

*Represents 88 plaques of a 1/10 dilution of input virus multiplied by 10.

Table 2 Release of oncornavirus RDDP by human serum

Enzyme source	Virus source	Serum type	c.p.m. polymerised ³ H-TTP	
			Fresh serum	Heated serum
None-H ₂ O	—	—	327	376
Purified RDDP*	—	Normal	1,070	943
Avian myeloblastosis virus	Chicken serum	Normal	728	350
Feline leukaemia virus	NCI	Normal	6,280	1,169
Feline leukaemia virus	NCI	C4 depleted	849	842
Moloney leukaemia virus	YCAB cells	Normal	2,153	466
Moloney leukaemia virus	YCAB cells	C2 deficient	587	587
Moloney leukaemia virus	SCRF 179 cells	Normal	3,064	393
Moloney leukaemia virus	SCRF 179 cells	C4 depleted	495	474
Rauscher leukaemia virus	NCI	Normal	2,383	897
Rauscher leukaemia virus	NCI	C2 deficient	730	696
Simian sarcoma virus	NCI	Normal	708	452
Wild mouse virus 1504	Wild mouse 1504 embryo cells	Normal	1,055	343

Enzyme source (25 μ l) was incubated with 25 μ l fresh or heated (56 °C, 30 min) human serum for 30 min at 37 °C. After incubation an equal volume of RDDP assay mix was added to the RDDP-serum solution, and the samples were again incubated at 37 °C for 30 min. The assay mix contained 1.25 mM MnCl₂; 0.05 M Tris buffer, pH 8.2; 20 mM dithiothreitol; 100 μ M deoxyadenosine 5'-triphosphate, 100 μ M deoxycytidine 5'-triphosphate; 100 μ M 2-deoxyguanosine 5'-triphosphate; 10 μ M thymidine 5'-triphosphate; poly(rA)-oligo(dT)₁₂₋₁₈ (0.33 U ml⁻¹) and thymidine-methyl-³H 5'-triphosphate (100 μ Ci ml⁻¹, specific activity 18 Ci mmol⁻¹). Polymerised ³H-TTP was counted in Aquasol after collection on DEAE filters and subsequent washes with 5% Na₂HPO₄, water, ethanol and ether¹². The degree of RDDP release caused by serum (which influences the RDDP assay) compared with NP40 varied greatly with each virus preparation and depended on virus concentration and amount of inactivated virus. For instance, this preparation of feline leukaemia virus released 108,000 c.p.m. of enzyme activity after NP40 treatment, whereas the simian sarcoma virus preparation released only 8,200 c.p.m. after NP40 treatment.

*Purified RDDP was from MLV.

detected at serum dilutions up to 1:8. Since RDDP is located within the virion, the release of this enzyme is a measurement of viral lysis. All normal sera from 32 separate humans tested but none from six individual guinea pigs, four individual rabbits, or pools from two separate strains of mice (BALB/c, NIH Swiss) caused the release of RDDP. The tested normal human sera were from five different cord blood samples and from six leukaemic and 21 healthy adults of both sexes with functional complement (C) activity.

Table 2 also shows that human sera genetically deficient in C2 or immunochemically depleted of C4 failed to release RDDP. These observations, coupled with the finding that all tested fresh normal sera released RDDP, suggested that C was required for the viral lysis. Consistent with this interpretation is the finding of C activation by MLV. After mixture of 200 μ l of fresh human serum with 200 μ g of purified MLV (in 200 μ l) for 60 min at 37 °C, 89% of the total complement haemolytic 50% endpoint (CH₅₀) units were consumed. Comparable C consumption was also observed when the reaction of serum with MLV was carried out in the presence of RNase (2.3 mg ml⁻¹) and DNase (1.6 mg ml⁻¹) (final concentrations in the serum-virus mixture), indicating that viral or contaminating cellular RNA or DNA was not responsible for the observed consumption of C. Haemolytic C component titrations¹³ in serum incubated with virus revealed significant consumption of the terminal components of C, that is C8 (40% above background) and C9 (20% above background), which are required for membrane lysis in other systems^{13,14}. In addition, the conversion of C3 and C4 in the serum was demonstrated by immunoelectrophoresis.

We were unable to establish a role for antibody in this reaction after trying four methods. First, fluoresceinated monospecific antisera against human IgA, IgG or IgM failed to stain the surfaces of SCRF 179 (MLV) cells which had previously been incubated with human serum. These cells demonstrated cell surface MLV antigens detectable by immunofluorescence with rat antibodies to MLV. Second, human serum heated at 56 °C for 30 min failed to inhibit oncornavirus plaque formation or to release RDDP either alone or in conjunction with fresh guinea pig or rabbit sera. Third, sera from two agammaglobulinaemic patients released RDDP from oncornavirions. These sera had less than 10 μ g IgG per ml and no detectable IgA or IgM. Fourth, fresh human serum retained its ability to release RDDP from oncornaviruses (MLV and feline leukaemia

virus) after absorption with SCRF 179 (MLV) cells. (This serum was absorbed twice with 1×10^7 cells for 40 min at 4 °C in the presence of 0.01 M EDTA. Before use, the EDTA in the serum was neutralised with CaCl₂.)

To rule out the possibility that lysis of oncornaviruses occurred because of C activation by components of foetal calf serum retained on the viral surface, we purified MLV from SCRF 179 (MLV) cells grown in medium containing heat-inactivated human serum in place of foetal calf serum. When mixed 1:2 with fresh human serum, these virions released significant amounts of RDDP and did not form plaques on XC cells (control without serum-3180 PFU, heated serum-2880 PFU, fresh serum-0 PFU). Avian myeloblastosis virus purified directly from chicken serum also released RDDP on incubation with fresh human serum (Table 2), and MLV obtained directly from a 1:10 dilution of mouse plasma (14,500 PFU) was inactivated by a 1:2 dilution of fresh human serum (heated human serum—confluent (>5,000) PFU, fresh human serum—263 PFU). Fresh guinea pig serum did not reduce plaque formation by this same MLV preparation from mouse plasma.

Our results demonstrate that all tested human sera with functional C sources inactivate and lyse avian, feline, murine and simian oncornaviruses. Whether a similar mechanism inactivates other enveloped viruses is unknown and is under study in our laboratory. C seems to be a mediator of this lytic mechanism, since human sera deficient in C2 or C4 do not release RDDP from oncornaviruses. In contrast, we found no evidence for antibody involvement in this reaction. Not only did agammaglobulinaemic human sera lyse oncornaviruses, but absorption of normal human serum with cells expressing surface oncornavirus antigens also failed to remove its cytolytic potential, and heated human serum was unable to sensitise oncornaviruses for lysis with guinea pig C. These findings suggest either that trace amounts of heat-labile antibody are present or that human C but not guinea pig, rabbit or mouse C can be directly activated by oncornaviruses. Similar activation of C in the absence of antibody has been reported in other systems^{15,16}. Whether serum factors other than C or antibody are involved is not known. If oncornaviruses do infect man, lysis of these viruses may represent a natural resistance mechanism which would limit horizontal oncornavirus transmission and serve to maintain vertically transmitted oncornaviruses in a repressed, defective or latent state. It would be interesting to examine the status of the C system

in individuals with neoplasia and to determine the incidence of malignancies and oncornavirus expression in humans with deficiencies in the C system.

Presence of antibody to a primate RNA virus in human plasma

AN antigen is present in leukocytes of patients with chronic myelogenous leukaemia (CML) which cross reacts with an antigen of the core protein of an RNA virus originally isolated from a Rhesus monkey, the Mason-Pfizer monkey virus (MPMV). This finding depended on development of a radioimmune assay using rabbit antibody raised against MPMV¹. I report here that using a modified Farr technique² plasma from some patients with various malignancies has antibody which reacts the MPMV core protein. The inference is that individuals in the human population may have been infected with a virus which is identical with or has antigens similar to those of the MPMV virus. The possible relevance of such infections to development of malignancies has yet to be determined.

A major protein of MPMV having a molecular weight of 25,000 (p25) was purified by a combination of Agarose gel filtration and DEAE-cellulose column chromatography. For a typical purification experiment, 10 ml of concentrated MPMV (5×10^{10} - 10^{11} particles ml⁻¹) grown in NC-37 cells were disrupted by exposure to 1% NP40 at 4 °C for 2-3 h. The mixture was separated on an Agarose A 0.5 M (BioRad) column (1.5 cm × 90 cm) equilibrated with 0.1% NP-40 in TNE (0.01 M Tris-HCl (pH 8.3), 0.15 M NaCl, 0.002 M ethylenediamine tetra-acetate) buffer. The peak containing p25 was applied to a DEAE-cellulose column (1.5 cm × 15 cm) equilibrated with 0.02 M phosphate buffer (pH 7.5) and eluted with 0.15 M sodium chloride. The isolated p25 was more than 95% pure as estimated by sodium dodecyl sulphate (SDS)-polyacrylamide gel electrophoresis. The p25 was iodinated with ¹²⁵I by the chloramine T procedure³. A goat anti-rabbit antiserum gave a maximum of 72% indirect precipitation of a mixture of ¹²⁵I-p25 and a rabbit antiserum prepared against MPMV. This indirect radio-precipitation was inhibited by MPMV virus obtained from

Fig. 1 The levels of antibody in each plasma are represented by the symbols. The individuals studied have been arbitrarily grouped in broad categories as indicated; the height of the bar represents the mean for each group. Myelogenous leukaemia group: ●, AML; ○, CML. Other tumours: ■, melanoma; □, osteosarcoma; ▲, carcinoma of larynx; ▽, acute lymphatic leukaemia; △, liposarcoma. Aliquots of heparinised plasma (200 µl) were incubated with ¹²⁵I-MPMV p25 and precipitated with 14% Na₂SO₄ as described in the legend of Table 1. The amount of ¹²⁵I-p25 precipitated by a plasma was converted to the percentage of ¹²⁵I-p25 precipitated assuming that the rabbit anti-MPMV precipitated 100% and the rabbit anti-MMTV precipitated 0%.

either cultures of human (NC-37) or simian (MT) cells infected with the virus. Proteins obtained from viral density region of disrupted non-infected NC-37 or simian cells (that is, in the region of 1.15-1.19 g ml⁻¹ in a sucrose density gradient) did not, however, cause any detectable inhibition of precipitation. Apparently then, the p25 is a viral protein and not a membrane component of the host cell, a finding in agreement with previous reports⁴.

In preliminary observations the conditions for an assay to be used for a survey of human plasmas were set. The percentage of ¹²⁵I-p25 precipitated with 14% sodium sul-

The volume of each sample was adjusted to 400 µl with 0.1% BSA in TNE buffer. ¹²⁵I-MPMV p25, 2-3000 c.p.m. of specific activity of 5×10^6 c.p.m. µg⁻¹ was added to the sample and incubated 1 h at 37 °C. Final concentration of 14% Na₂SO₄ was made with 25% Na₂SO₄ solution followed by an additional 1 h incubation at 37 °C. Two-thirds of the supernatants (sup) were counted separately from the precipitates (ppt) with remaining supernatants. Then the percentage precipitation was calculated: % ppt = 100 [(ppt + 1/3 sup) - 1/2 (2/3 sup)] / [(ppt + 1/3 sup) + (2/3 sup)]. Aggregation of ¹²⁵I-p25 was minimised by storing in TNE buffer containing 10% glycerol and 1% Triton X-100. ¹²⁵I was prepared fresh every third week for the assays. In these conditions less than 4% of p25 was precipitable by 14% Na₂SO₄ without added plasma.

phate was measured using dilutions of plasma ranging from 1:2 to 1:16 (Table 1). Accurate quantitation of antibody present in large amounts in the rabbit anti-MPMV serum would require high dilutions of plasma. However, a plasma dilution of 1:2 would permit qualitative demonstration of antibody in plasmas containing either a great deal or only small amounts of antibody to ^{125}I -p25 as shown for two human sera (Table 1).

The binding of ^{125}I -p25 is at least partially due to IgG in the plasmas as shown in the following way. IgG was purified from various rabbit and human plasmas by successive 18% and 14% Na_2SO_4 precipitations followed by DEAE-cellulose column chromatography. A single typical IgG precipitin arc was obtained for each preparation on immunoelectrophoresis using appropriate goat anti-human or anti-rabbit serum. Forty milligrams of each purified Ig was coupled to 4 ml of CNBr activated Sepharose. For each immunoabsorbent column, 1 ml of Sepharose was used. Radiolabelled antigens (^{125}I -p25, 51,000 c.p.m.; ^{125}I -BSA, 57,000 c.p.m.) were added to the column and incubated for 2 h at room temperature. The Sepharose columns were washed with $\times 20$ volumes of 0.2% ovalbumin in TNE buffer to remove unbound radiolabelled antigens. Successive elutions were made with 5 ml of 0.1 M glycine-HCl buffer (pH 2.3) and 6 M guanidine-HCl. As shown in Table 2, the purified Ig which was obtained from whole plasma bound ^{125}I -p25 specifically.

The survey of plasmas for antibody against ^{125}I -p25 was done on samples from 75 individuals, 67 of whom had a clinical diagnosis of malignancy and eight of whom were apparently healthy volunteers including three normal pregnant women. The samples were obtained from patients at Billings Hospital, University of Chicago and Presbyterian Hospital, Columbia University, New York. These donors were selected without regard to age, sex, stage or type of the malignancy or therapy.

The percentage of ^{125}I -p25 bound by each plasma is plotted in Fig. 1. The individual responses for 8 normal volunteers, 8 patients with carcinoma of the rectum, 12 patients with carcinoma of the lung, 13 patients with carcinoma of the breast and 9 patients with other malignancies range from 15 to 25% binding of ^{125}I -p25; differences between the means of these groups are not statistically significant ($P > 0.05$). Patients with carcinoma of the colon and leukaemia, however, had levels as high as 66–70% binding, furthermore, plasmas from only single individuals in each of these groups have less antibody than the normal individual with the highest level of binding. The significance levels of differences between the means are: $P < 0.005$ for patients with carcinoma of the colon and the normal group and $P < 0.001$ for patients with leukaemia and the normal group.

These results suggest that some individuals may have

been or are infected with a virus similar to or identical with MPMV. The demonstration of an antigen in leukocytes of patients with CML¹ is consistent with this possibility. In so far as it has been examined, antigens cross reactive with p25 of MPMV have not been found in other C type RNA viruses, but such cross reactions might be found on more extensive survey using highly sensitive radioimmune assays.

Patients with leukaemia or carcinoma of the colon may simply be more prone to exposure and/or infection with the agent responsible for inducing antibody against p25 of MPMV. Alternatively, of course, the infection may be relevant to development of malignancy. MPMV-like particles have been identified in human cell lines derived from a leukaemia or other malignancies^{5–7}, as well as from spontaneously transformed normal cells^{8,9}. The MPMV has morphological, biochemical and biophysical characteristics of known oncornaviruses^{10,11} though they have not been shown to share immunologic characteristics^{4,8}. Considerable evidence now supports the general proposition that viruses have aetiological significance in leukaemogenesis in humans¹² as well as in mice¹³. In mice, humoral antibodies to endogenous or exogenous leukaemia viruses presumably reflect exposure to the virus^{14,15}; the demonstration here of antibody to p25 of MPMV may have analogous significance. This possibility might be best studied in humans with CML, since leukocytes from such patients contain a protein antigenically cross reactive with p25 of MPMV and plasma from many such patients contains considerable antibody to the antigen. Furthermore, long remissions of the disease often occur. Therefore, in studies under way, changes which may occur in levels of the leukocyte antigen and in plasma levels of antibody will be studied during the course of the disease.

I thank Dr Donald A. Rowley for his support and help with this manuscript, and Drs John Hopper, Stanley Yachin and Ms Susan Schulman for providing blood specimens. This study was supported by a grant from the Leukaemia Research Foundation.

Discrimination between eukaryotic and prokaryotic, and formylated and non-formylated, initiator tRNAs by eukaryotic initiation factor EIF-3

PROKARYOTIC and eukaryotic cells contain two methionine accepting species of transfer RNA, tRNA^{Met} and tRNA^{Met} prokaryotes⁴ and non-formylated Met-tRNA_i in prokaryotes⁴ and non-formylated Met-tRNA_i from eukaryotes⁵⁻⁹ act exclusively in chain initiation; Met-tRNA_m provides amino acids for internal positions in proteins⁴⁻⁹. Thus the structure of tRNA^{Met} is likely to have some unique attribute that makes it specific for initiation and that provides for its recognition by initiation factors¹⁰⁻¹³. We have investigated the specificity of an eukaryotic initiation factor (EIF-3) for initiator tRNA. A preparation of EIF-3 formed a complex preferentially with nonformylated eukaryotic Met-tRNA_i; the factor discriminated against the formylated eukaryotic species and against prokaryotic initiator tRNA whether it was formylated or not. A preliminary account of the experiments has been reported before¹⁴.

We have isolated EIF-3 from mouse Krebs II ascites cells by chromatography of a 0.25 M KCl ribosomal salt wash on DEAE-Sephadex and hydroxylapatite (details of the isolation of EIF-3 will be presented elsewhere). EIF-3, like initiation factor IF-2 from *E. coli*¹¹⁻¹², forms a ternary complex with GTP and eukaryotic Met-tRNA_i; the ternary complex is quantitatively retained on Millipore filters. The factor does not form a ternary complex with Met-tRNA_m or other tRNA species. A similar factor has been prepared from rabbit reticulocytes and L cells¹⁵⁻¹⁸. The preformed ternary complex is transferred to 40S ribosomal subunits in the absence of mRNA. The nature of the partial reactions catalysed by EIF-3 (that is the formation of the ternary complex and its transfer to 40S ribosomal subunits) suggests that the factor is involved in the recognition of Met-tRNA_i, and is therefore an intermediate in the formation of a 40S preinitiation complex.

We compared the recognition by EIF-3 of eukaryotic and prokaryotic Met-tRNA_i and fMet-tRNA_i. EIF-3 formed a ternary complex with GTP and yeast or ascites cell Met-tRNA_i very rapidly (Fig. 1); however, there was little (only about 15% as much) ternary complex formation when *E. coli* Met-tRNA_i was used (Fig. 1). Formylated prokaryotic Met-tRNA_i was an even poorer substrate for EIF-3 (Fig. 1). Similar results were obtained when complex formation was measured as a function of the amount of EIF-3 (Fig. 2).

We next investigated whether EIF-3 distinguished between formylated and non-formylated Met-tRNA_i (Table 1). Although EIF-3 clearly used non-formylated eukaryotic (yeast or ascites cell) Met-tRNA_i preparations more efficiently than the formylated variety, it appeared that the factor would form a complex with the formylated species, albeit only 35-50% as well (Table 1). The formylation reaction was, however, only 65-80% effective; thus complex formation could have been with contaminating non-formylated Met-tRNA_i. Indeed, when a preparation of ascites cell fMet-tRNA_i that contained 9,400 c.p.m. and was 64% formylated was incubated with GTP and increasing amounts (up to 20 µg) of EIF-3, the radioactivity in the ternary complex, when a plateau was reached, was 4,300 c.p.m.; binding was maximum with less than 10 µg of EIF-3

Fig. 1 Kinetics of ternary complex formation with EIF-3, GTP and eukaryotic or prokaryotic initiator tRNA. The reaction mixture for the eukaryotic initiator tRNA experiments contained in 100 µl of buffer A (20 mM Tris-HCl, pH 7.6; 100 mM KCl; 0.2 mM magnesium acetate, and 1 mM dithiothreitol): 34.2 µg of EIF-3; 0.2 mM GTP; and 200 µg of ascites cell tRNA containing 76,000 c.p.m. of ³H-Met-tRNA_i, or 125 µg of yeast tRNA containing 65,000 c.p.m. of ³H-Met-tRNA_i. For the prokaryotic initiator tRNA experiments, 150 µl of buffer A contained: 51.3 µg of EIF-3; 0.2 mM GTP, and 19 µg of *E. coli* tRNA^{Met} with 66,600 c.p.m. of ³H-Met-tRNA_i or 17.3 µg of *E. coli* tRNA^{Met} with 74,000 c.p.m. of formyl-³H-Met-tRNA_i. Samples were incubated at 30 °C; at intervals, 25-µl samples were removed and the formation of a ternary complex determined by filtration on Millipore filters. The filters were washed three times with 3 ml of buffer A. The filters were dried and placed in glass vials containing 5 ml of scintillation fluid¹⁹. Radioactivity was determined in a Packard Tri-Carb spectrometer with an efficiency of 16%. The tRNA^{Met} species was prepared from unfractionated ascites cell tRNA or from yeast tRNA by chromatography on BD-cellulose⁶. The purified *E. coli* tRNA^{Met} was obtained from Oak Ridge National Laboratory. The tRNA was charged with ³H-methionine (4.3 Ci mmol⁻¹) using a preparation of *E. coli* aminoacyl-tRNA synthetases^{3,20}. When ³H-Met-tRNA_i was to be formylated, tetrahydrofolic acid (Leucovorin, Lederle Laboratories) was included in the reaction mixture²¹ and the extent of formylation was determined by paper chromatography of a deacylated sample²¹. ■, Yeast Met-tRNA_i; △, ascites Met-tRNA_i; ○, *E. coli* Met-tRNA_i; ●, *E. coli* fMet-tRNA_i.

(results not shown). The results are by no means conclusive, but since EIF-3 prefers the non-formylated species they are consistent with complex formation having occurred predominantly, if not exclusively, with the non-formylated Met-tRNA_i that was present.

We sought to confirm our impression that it was chiefly non-formylated Met-tRNA_i contaminating preparations of fMet-tRNA_i that was responsible for ternary complex formation (Table 2). The complex formed with EIF-3, GTP and partially (64%) formylated Met-tRNA_i was isolated on Millipore filters and digested with pancreatic RNase. The amount of Met-tRNA_i, as methionyl-adenosine and fMet-tRNA_i, as formyl-methionyl-adenosine²², in the RNase digest was determined after extraction with ethyl acetate²³. Only about 14% of the ternary complex contained fMet-tRNA_i. The predominant species in the complex (85-90%) was Met-tRNA_i. Cashion and Stanley²⁴ have reported similar results: they found a like amount (10%) of ternary complex formation when formylated eukaryotic Met-tRNA_i, rather than the non-formylated species, was tested with an initiation factor (IF_i) from rabbit reticulocytes.

Table 1 Discrimination by EIF-3 between eukaryotic and prokaryotic initiator tRNA

Initiator tRNA	Aminoacyl-tRNA bound (pmol)
Met-tRNA _f (ascites)	3.53
fMet-tRNA _f (ascites) (70% formylated)	1.28
Met-tRNA _f (yeast)	3.55
fMet-tRNA _f (yeast) (80% formylated)	1.80
Met-tRNA _f (<i>E. coli</i>)	0.59
fMet-tRNA _f (<i>E. coli</i>) (99% formylated)	0.11

The reaction mixture (25 μ l in buffer A) contained: 5.7 μ g of EIF-3; 0.2 mM GTP; and 40 μ g of ascites cell tRNA containing 13,800 c.p.m. of ³H-Met-tRNA_f, or 84 μ g of ascites cell tRNA containing 10,400 c.p.m. of formyl-³H-Met-tRNA_f, or 25 μ g of yeast tRNA containing 13,000 c.p.m. of ³H-Met-tRNA_f, or 24 μ g of yeast tRNA containing 16,000 c.p.m. of formyl-³H-Met-tRNA_f, or 3.1 μ g of *E. coli* tRNA_f^{Met} containing 11,100 c.p.m. of ³H-Met-tRNA_f, or 2.9 μ g of *E. coli* tRNA_f^{Met} containing 12,400 c.p.m. of formyl-³H-Met-tRNA_f. Incubation was at 30 °C for 5 min and the complex was assayed on Millipore filters.

Once again there was little ternary complex formation with EIF-3, GTP and prokaryotic Met-tRNA_f; however, even that small amount was reduced if *E. coli* Met-tRNA_f was formylated (Table 1).

The eukaryotic initiation factor EIF-3 shows a clear preference for non-formylated eukaryotic Met-tRNA_f. Formylation decreases the ability of the eukaryotic initiator tRNA to serve as a substrate for EIF-3, and prokaryotic Met-tRNA_f, whether formylated or not, serves especially poorly in the reaction. The observations are consistent with the finding reported by Heckman *et al.* (J. Heckman, G. Temple, C.L. Woodley, N.K. Gupta and U.L. RajBhandary, personal communication) that prokaryotic Met-tRNA_f is much less efficient (20–30%) than eukaryotic Met-tRNA_f in the translation of haemoglobin mRNA in mouse Krebs II ascites extracts. It is likely that the results reflect differences in the structure of eukaryotic and prokaryotic initiator tRNAs, initiation factors, or both. There is no extensive homology in the nucleotide sequence of initiator tRNAs from *E. coli*²⁵ and eukaryotes^{26–28}, and the initiation factors are almost certainly different.

The efficient formation of a ternary complex between mouse ascites cell EIF-3 and Met-tRNA_f from yeast, a phylogenetically distant eukaryote, implies conservation of the recognition sites. Indeed, the results were to be expected since the nucleotide sequence of initiator tRNAs from higher eukaryotes (rabbit liver²⁷, sheep mammary gland²⁷ and mouse P3 myeloma²⁸) have extensive homology with yeast initiator tRNA²⁶.

Lodish *et al.*²⁹ had reported that yeast fMet-tRNA_f was

used as effectively as Met-tRNA_f in initiation of protein synthesis by rabbit reticulocyte ribosomes. On the other hand, other available results^{8,30,31} more nearly approximated ours: that the incorporation of formylmethionine from eukaryotic fMet-tRNA_f into polypeptides in mouse Krebs II ascites extracts was slow and never very extensive when compared with that with Met-tRNA_f. The conflict may reflect to some degree difference in the cells used, but it may be important that in the experiments of Lodish *et al.*²⁹ high concentrations of purified initiator tRNA were used, concentrations so high as to risk dampening the differences in efficiency of incorporation from Met-tRNA_f and fMet-tRNA_f. The observations emphasise the great importance of using physiologically proper substrates for studying the partial reactions in the initiation of protein synthesis.

This research was supported by grants from the National Institutes of Health and funds from the University of

Fig. 2 Effect of the amount of EIF-3 on the formation of a ternary complex with eukaryotic or prokaryotic initiator tRNA. The reaction mixture (25 μ l in buffer A) contained: EIF-3 (as indicated); 0.2 mM GTP; and 100 μ g of ascites cell tRNA containing 25,000 c.p.m. of ³H-Met-tRNA_f, or 37.5 μ g of yeast tRNA containing 19,500 c.p.m. of ³H-Met-tRNA_f, or 2.9 μ g of *E. coli* tRNA_f^{Met} containing 12,400 c.p.m. of formyl-³H-Met-tRNA_f, or 3.1 μ g of *E. coli* tRNA_f^{Met} containing 11,000 c.p.m. of ³H-Met-tRNA_f. Incubations were at 30 °C for 5 min. Samples were assayed as described in Fig. 1. Symbols as in Fig. 1.

Table 2 Ternary complex formation with EIF-3 and fMet-tRNA_f or Met-tRNA_f

Sample	Met-tRNA _f or fMet-tRNA _f bound to Millipore filter (pmol)	Met-tRNA _f or fMet-tRNA _f remaining bound to Millipore filter after RNase digestion (pmol)	fMet-tRNA as fMet-adenosine in ethyl acetate phase (pmol)	Met-tRNA _f as Met-adenosine in aqueous phase (pmol)
Control	1.94	—	—	—
Digested with RNase and extracted with ethyl acetate	—	0.30	0.19 (13.7%)	1.20 (86.3%)

The reaction mixture (25 μ l in buffer A) contained: 7.6 μ g of EIF-3; 59.5 μ g of tRNA containing 12,200 c.p.m. of ³H-fMet-tRNA_f (64% formylated); and 0.2 mM GTP. Incubation was for 5 min at 30 °C. The EIF-3·GTP·Met-tRNA_f or EIF-3·GTP·fMet-tRNA_f complex was collected on Millipore filters. One group was used to determine the total amount of complex formed; the other was digested with (6 μ g) pancreatic RNase in 1 ml of 0.1 M potassium acetate buffer, pH 5.5 at 30 °C for 15 min. The complex remaining bound to Millipore filters was assayed (see Table). The fMet-tRNA_f as fMet-adenosine²² in potassium acetate buffer (pH 5.5) was extracted with ethyl acetate according to Leder and Bursztyn²³ and the Met-tRNA_f as Met-adenosine²³ remaining in the aqueous phase was determined. The values are the average of duplicate samples.

Blocked, methylated 5'-terminal sequence in avian sarcoma virus RNA

mRNAs of many eukaryotic cells and viruses contain blocked, methylated 5'-terminal structures of the type, m⁷GpppN (ref. 1). This 'cap' structure, and in particular the 5'-terminal 7-methyl-guanosine, is required for efficient translation *in vitro* of globin, reovirus and vesicular stomatitis virus mRNAs^{2,3}. The genome subunits of RNA tumour viruses probably function as viral mRNA since RNA of the same base sequence is present in virus-specific polysomes of infected cells^{4,5} and virion genome RNA can be translated *in vitro* in a eukaryotic system⁶. Consistent with this possibility, we have found a blocked, methylated 5'-terminal structure—m⁷GpppG^mpCp—in the genome RNA of avian sarcoma virus (ASV).

Subunits of ³²P-labelled B77-ASV genome RNA were isolated by rate-zonal centrifugation of denatured viral RNA as described previously⁷. RNA from about the 35S region of the gradient migrated in the vicinity of 35S poliovirus RNA when analysed by polyacrylamide gel electrophoresis. The latter procedure resolved the a (35S) and b (smaller than 35S) RNA subunits which correspond to transforming and transformation defective particles⁸ present in the virus stock at levels of 20% and 80% respectively. The RNA hybridised completely with virus-specific DNA synthesised *in vitro* (data not shown).

To test for the presence of blocked 5' termini in ASV genome RNA, we used a procedure developed originally for the isolation of 3'-terminal oligonucleotides from high molecular weight RNA⁹. It depends on the selective affinity of 2'-3' *cis* diols for

DBAE-cellulose, a derivative with covalently bound dihydroxyboryl groups. ASV ³²P-labelled genome RNA was mixed with ³H-methyl-labelled reovirus mRNA, digested to completion with RNase T₂, and applied to a column of DBAE-cellulose. The 5'-terminal RNase T₂ fragment of reovirus mRNA, m⁷G(5')ppp(5')G^mpCp, contains all the methyl groups of the viral RNA and free 2',3'-hydroxyl groups in the 5'-terminal m⁷G (ref. 10). Consequently, the ³H-methyl radioactivity bound quantitatively to DBAE-cellulose in buffer A (Fig. 1). Most of the ³²P-labelled digestion products consisted of 3' mononucleotides and did not bind; however, 0.08% of the ³²P bound to the resin and, after changing the buffer, eluted with the ³H-labelled m⁷GpppG^mpCp. The 3'-terminal adenosine released by RNase digestion¹¹ presumably bound but contained no ³²P and was undetected. This value is in excellent agreement with the expected amount of DBAE-bound ³²P calculated for approximately 35S RNA (7,500 nucleotides) containing a RNase T₂-resistant, 5'-5'-linked cap structure similar to that in reovirus RNA¹⁰ (5 phosphates).

The RNase T₂ digested mixture of ³²P-labelled ASV fragments and ³H-labelled m⁷GpppG^mpCp was eluted from DBAE-

Fig. 1 Chromatography of RNase T₂ digest of ³²P-labelled ASV genome RNA on DBAE-cellulose. The B77 strain (sub-group C) of ASV was propagated in chick embryo fibroblasts, isolated by centrifugation and the viral RNA extracted with Pronase-sodium dodecyl sulphate-phenol, all as described previously⁷. Growth medium (phosphate-free) containing dialysed calf serum (see ref. 7 for details) and ³²P-orthophosphate (2 mCi ml⁻¹) was changed every 12 h for a total of three collections; viral RNA labelled in this manner had a specific activity of 15 × 10⁶-30 × 10⁶ c.p.m. μg⁻¹. The 70S genome RNA was isolated by rate-zonal centrifugation⁷, dissolved in 0.01 M EDTA-0.02 M Tris-HCl, pH 7.4-0.5% (w/v) SDS, heated at 80 °C for 4 min and centrifuged through a gradient of 15-30% sucrose containing 0.1 M NaCl-0.01 M EDTA-0.02 M Tris-HCl, pH 7.4-0.5% SDS. Centrifugation was in a Spinco SW 27.1 rotor at 25,000 r.p.m. for 15 h at 20 °C. The gradient was fractionated and radioactivity in the fractions measured as Cerenkov radiation. ASV genome RNA, 1.1 × 10⁷ c.p.m., was mixed with ³H-methyl-labelled reovirus mRNA synthesised *in vitro* (10 μg, 1 × 10⁵ c.p.m.) and digested with 50 units RNase T₂ (Sankyo) in 250 μl of 10 mM sodium acetate buffer (pH 4.5) containing 1 mM EDTA. After incubation for 6 h at 37 °C, the reaction mixture was adjusted to starting buffer A (0.05 M morpholine, pH 8.7, 1.0 M NaCl, 0.1 M MgCl₂, 20% dimethylsulphoxide) in a total volume of 1 ml. The mixture was applied on to a DBAE-cellulose column (0.6 × 15 cm) equilibrated with buffer A (ref. 9). Elution was carried out with buffer A at a flow rate of 5 ml h⁻¹. When most of the radioactive material had been eluted from the column, the buffer was abruptly changed to buffer A plus 1 M sorbitol and elution continued at a flow rate of 6-7 ml h⁻¹. ³²P radioactivity was determined by Cerenkov counting and ³H radioactivity measured by dissolving an aliquot (25 μl) of each fraction in 1 ml methyl-cellosolve and 10 ml Aquasol (New England Nuclear). ○, ³²P; ●, ³H.

Table 1 Methylated nucleosides derived from 70S and 4S ASV RNA

	70S-I	Free 4S	70S-II	35S
m ⁷ G	13*	18	20	2
mC	14	17	21	3
mA	—	1	—	—
mG+mU	36	64	59	10
cap m ⁷ G	5	0	—	14
cap G ^m	5	0	—	
m ⁶ A	27	—	—	71
Total c.p.m.	4,227	10,689	2,654	1,048

*Value given in % of total ³H-methyl radioactivity.

Two 100-mm plates of transformed, B77-infected chick cells were incubated for 10 h in 5 ml of amino acid-free medium containing dialysed serum, 10⁻⁴ M each of adenosine and guanosine, and 500 μ Ci ml⁻¹ of ³H-methyl-methionine (specific activity 10.5 Ci mmol⁻¹, New England Nuclear). The medium was collected, fresh medium of the same composition but lacking radioisotope was added, and collected after 10 h and pooled with the first collection. The virus was collected by pelleting, disrupted in 0.02 M Tris buffer, pH 7.4, containing 0.15 M NaCl, 0.001 M EDTA and 0.5% sodium dodecyl sulphate and the 70S and 4S RNA separated by density gradient centrifugation⁷. The 35S RNA was obtained from 70S RNA after denaturation and centrifugation as described for Fig. 1. The RNA-containing fractions were pooled, precipitated with ethanol, digested with *Penicillium* nuclease and alkaline phosphatase, and analysed by paper electrophoresis at pH 3.5 as described in Fig. 2 (ref. 10). The radioactivity in the region corresponding to methylated derivatives of adenosine in the 70S RNA digest was eluted and identified by paper chromatography with authentic marker N⁶-methyladenosine in two different solvents: isobutyric acid–0.5 M NH₄OH (10:6 v/v) and isopropanol–concentrated NH₄OH–H₂O (7:1:2 v/v). The nuclease- and phosphatase-resistant radioactivity in presumptive caps of 70S RNA was eluted, treated with nucleotide pyrophosphatase and alkaline phosphatase and the digest was analysed by paper electrophoresis and identified as consisting of equal amounts of m⁷G and G^m by subsequent paper chromatography with authentic marker compounds¹⁸. For comparison of the composition of free and 70S genome-associated 4S RNA, values in column (70S-II) were calculated from (70S-I) after omitting the radioactivity in caps and N⁶-methyladenosine. mC, mA, mG, mU are methylated derivatives of the corresponding nucleosides that were not identified further.

cellulose, desalted and reanalysed by DEAE–cellulose chromatography to determine its net charge¹⁰. Two peaks of ³²P with net charges of –4.5 and –5 were resolved, and both contained a corresponding proportion of ³H-methyl radioactivity (Fig. 2). The fractions comprising the major peak were pooled, desalted, digested with *Penicillium* nuclease (P₁) and analysed by paper electrophoresis. P₁ hydrolyses phosphodiester linkages, including those containing 2'-O-methylated residues, to yield 5' mononucleotides from polynucleotides. The enzyme also has 3' phosphatase activity, but cannot cleave cap structures^{10,12}; thus, ³H-methyl-labelled m⁷GpppG^mpCp, derived from reovirus mRNA by RNase T₂ digestion, yielded all the radioactivity as m⁷GpppG^m after P₁ treatment (Fig. 2). By contrast, the ³²P-labelled material yielded radioactivity in the positions of pC, m⁷GpppG^m and Pi in a ratio close to 1:3:1 as expected for P₁ cleavage of m⁷GpppG^mpCp.

Another preparation of RNase T₂ 5'-terminal fragments was digested with P₁ and alkaline phosphatase and analysed by electrophoresis (Fig. 3a). The ³H-methyl-labelled 5'-terminal m⁷GpppG^mpCp was converted to m⁷GpppG^m. The ³²P-labelled fragments yielded 60% of the radioactivity in the position of m⁷GpppG^m and 40% as Pi. The ³H-labelled m⁷GpppG^m and the comigrating ³²P-labelled material were eluted and analysed by descending paper chromatography (Fig. 3b). All the ³H and ³²P radioactivity again comigrated, and the ratio of ³²P to ³H was constant across the peak. The position of the major peak of ³²P corresponded to that of m⁷GpppG^m. The minor peak (fractions 12–14) seemed to result from partial degradation during DBAE–cellulose chromatography at pH 8.7. This material and the smaller peak in Fig. 2a (fractions 90–95) consisted of the ring-opened derivative of m⁷GpppG^m, as determined by electrophoresis and chromatography of nucleotide pyrophosphatase digests. The major peak of radioactivity

Fig. 2 Characterisation of blocked 5'-terminal fragment from ASV genome RNA. *a*, The peak fractions eluted with buffer A containing 1 M sorbitol (Fig. 1) were diluted tenfold with water and applied to a DEAE–cellulose column (0.6×40 cm) equilibrated with 0.02 M Tris–HCl (pH 8.0) and eluted with a linear gradient of NaCl (0.05–0.3 M) in 0.02 M Tris–HCl buffer (pH 8.0) containing 7 M urea (total 150 ml). A pancreatic RNase digest of yeast tRNA was included as marker for the oligonucleotide elution positions. ³²P (●), and ³H (○) radioactivity were determined as described in Fig. 1. *b*, Peak fractions 82–88 were pooled as indicated, desalted, dissolved in 200 μ l of 5 mM sodium acetate buffer (pH 6.0) and digested with 100 μ g of P₁ nuclease at 37 °C for 30 min. The digest was analysed by high voltage paper electrophoresis in pyridine acetate buffer (pH 3.5) at 50 V cm⁻¹ for 50 min (ref. 10). ³²P, (—); ³H, (---)

(fractions 16–19) was eluted and an aliquot analysed by DEAE–cellulose chromatography; the ³H and ³²P eluted in one peak with a net charge between –2 and –3 (Fig. 3b, inset). The results are consistent with the presence of three phosphates in a phosphatase-resistant structure, previously demonstrated to be m⁷GpppG^m for reovirus mRNA 5' ends¹⁰. Similarly, when ³²P-labelled ASV genome RNA was digested with P₁ and alkaline phosphatase and analysed directly by electrophoresis, 0.04% of the total ³²P was obtained as a peak in the position of m⁷GpppG^m. This value is close to that calculated for one cap structure containing three protected phosphates per RNA molecule of chain length 7,500 nucleotides.

To determine if an identical 5' structure is present in ASV and reovirus RNA, an aliquot of P₁ and alkaline phosphatase-treated mRNA fragments (corresponding to fractions 16–19 in Fig. 3b) was digested with nucleotide pyrophosphatase and analysed by electrophoresis. The ³H-methyl radioactivity in m⁷GpppG^m was converted to equal amounts of m⁷pG and pG^m. The ³²P was resolved into three equally labelled constituents which migrated in the positions of m⁷pG, pG^m and Pi;

Fig. 3 Analysis of blocked 5'-terminal structure by electrophoresis and chromatography. Another preparation of 5'-terminal RNase T₂ fragments of ³H-methyl-labelled reovirus mRNA and ³²P-labelled ASV genome RNA was obtained as in Fig. 1. a, After desalting, the radioactive DBAE-cellulose-bound material was digested successively with P_i nuclease and alkaline phosphatase, and the digest analysed by paper electrophoresis; b, the enzyme-resistant radioactivity which migrated between pA and pG was extracted and chromatographed on paper using isobutyric acid-0.5 M NH₄OH (10:6 v/v) as a solvent. Inset, An aliquot of the material in fractions 16-19 of B was applied to a DEAE-cellulose column (0.6 × 25 cm) and eluted as described in Fig. 2a. ○, —, ³²P; ●, ---, ³H.

the nucleotides were eluted and further identified as m⁷pG and pG^m by paper chromatography. Thus the 5' termini of the ASV genome subunits probably have only one type of blocked, methylated structure, namely, m⁷GpppG^mpCp.

In addition to blocked, methylated 5'-terminal structures, poly(A)-containing RNA isolated from eukaryotic cells contains m⁶A in internal positions¹³⁻¹⁸. The same methylated nucleoside was found in ASV genome RNA (Table 1). Virion 70S RNA labelled with ³H-methyl-methionine contained 10% of the total radioactivity in m⁷GpppG^m and 27% in m⁶A, a methylated derivative of adenosine rarely found in tRNA¹⁹. Transfer (4S) RNA present in virions but not associated with the genome RNA contained no cap structures and only a low level of methylated adenosine; m⁷G and methylated derivatives of cytidine, guanosine and uridine were present as reported previously for 4S RNA in Rous sarcoma virus²⁰. The proportions of methylated nucleosides in free 4S RNA and 70S RNA were similar when calculated after subtracting the radioactivity in caps and m⁶A, consistent with the presence of the latter in genome subunit RNA (Table 1). Direct analysis of ³H-methyl-labelled approximately 35S RNA from denatured 70S RNA revealed that ASV genome RNA contained 71% of the total radioactivity in m⁶A and 14% in m⁷GpppG^m, sug-

gesting that there are about 10 residues of m⁶A per RNA subunit. On the basis that 4S RNA contains an average of 11 methylated nucleotides¹⁹, the number of 4S RNA molecules per genome subunit was estimated to be close to two.

ASV genome RNA, like cellular cytoplasmic mRNA, contains 5'-m⁷GpppN, 3'-terminal poly(A) and internal m⁶A and is probably formed by cellular mechanisms of mRNA biosynthesis. Poly(A)-containing RNA from the nuclei of HeLa cells also has m⁷GpppN at the 5' end¹⁸. It is not, however, known whether ASV genome RNA is 'capped' and methylated in the nucleus or in the cytoplasm of infected cells. Viral RNA may be made from larger precursor RNA by a processing mechanism involving concomitant addition of caps²¹. Alternatively, 'capping' of ASV genome RNA may occur at the initiation step of transcription in a manner analogous to mRNA synthesis and modification by virion-associated enzymes²²⁻²⁴. The same 5'-terminal sequence, m⁷GpppG^mpCp, has also been found in Prague strain Rous sarcoma virus 35S RNA (J. M. Keith and H. Fraenkel-Conrat, personal communication).

We thank Maureen Morgan and Karen Smith for technical assistance; Barbara Cordwell-Stewart assisted in the preparation of the viral RNA. This work was supported in part by a grant from the National Cancer Institute to J.M.B.

Thermodynamic activation parameters of fish myofibrillar ATPase enzyme and evolutionary adaptations to temperature

INTERSPECIFIC compensatory adaptations to environmental temperature which occur at the molecular level have been demonstrated for several enzyme systems¹. Most of these studies have been concerned with either kinetic parameters such as *K_m* (refs 2, 3) or thermodynamic parameters such as activation energy^{2,4}. The significance of changes in these parameters in the overall mechanism of evolutionary temperature

Table 1 Thermodynamic activation parameters for fish myofibrillar ATPase activity

Species	Approximate environmental temperature (°C)	Assay temperature (°C)	V _{max} (μmol Pi mg ⁻¹ min ⁻¹)	E _a (calorie mol ⁻¹)	No. assays	ΔH [‡] (calorie mol ⁻¹)	ΔS [‡] (entropy units)	ΔG [‡] (calorie mol ⁻¹)
<i>Nothenia rossii</i>	South Georgia, British Antarctica (0°–2 °C)	0.5	0.24			6,850	–42.2	18,450
		18	0.81	7,400**	21	6,800	–39.4	18,300
<i>Gadus virens</i>	North Sea (5°–14 °C)	0.5	0.06			10,200	–33.7	19,400
		18	0.82	10,700*	18	10,100	–28.1	18,900
<i>Gadus morhua</i>	North Sea (5°–14 °C)	0.5	0.07			11,350	–26.2	18,500
		18	0.61	11,900***	24	11,300	–24.6	19,050
<i>Amphiprion sebae</i>	Indian Ocean (about 23°–25 °C)	0.5	0.013			16,750	–9.6	19,400
		18	0.57	17,300*	18	16,700	–6.1	18,500
<i>Carassius carassius</i>	Domestic (Acclimatised to 26 °C)	0.5	0.03			21,400	8.3	19,050
		18	0.35	21,900*	18	21,300	8.6	18,800
<i>Tipalia nigra</i>	Equatorial African freshwater lake (23°–31 °C)	0.5	0.017			31,000	42.9	19,300
		18	0.045	31,600**	18	31,500	42.5	18,600

		18	0.69	33,300***	18	33,300	49.2	19,000

Myofibrils were prepared from the dorsal epaxial musculature as before¹¹, care was taken to exclude superficial red muscle as this has a different myofibrillar ATPase activity¹². The assay for ATPase activity was performed in 1.5 ml of 40 mM Tris-HCl (pH 7.5) with 6 mM ATP, 6 mM MgSO₄ and 0.2 mM CaCl₂ at $I = 0.12$ (adjusted with KCl) and at a myofibrillar concentration of 0.4–0.5 mg ml⁻¹. The reaction was terminated by addition of TCA and the Pi liberated was determined^{13,14}. Appropriate controls and reagent blanks were included in all experiments. Determinations of myofibrillar ATPase activity were made in triplicate at a series of temperatures between 0° and 18 °C. Activation energies (E_a) for the reactions over this temperature range were calculated from the corresponding Arrhenius plots. The Arrhenius plots were found to be linear within this temperature range for all species studied (statistical analyses given above). Thermodynamic parameters were calculated according to the following relationships¹⁵: $\Delta G^{\ddagger} = \Delta H^{\ddagger} - T\Delta S^{\ddagger}$; $\Delta H^{\ddagger} = E_a - RT$; $\Delta S^{\ddagger} = 4.576(\log K - 10.753 - \log T + E_a/4.576T)$ and $K (s^{-1}) = V_{max}$ per mg of enzyme \times molecular weight $\times 10^{-3}$ mmol μmol⁻¹ $\times 1$ min per 60 s, where the molecular weight is expressed as mg mmol⁻¹ and V_{max} as μmol mg⁻¹ min⁻¹. The proportion of myosin in the myofibril was assumed to be 54% (ref. 7), with a molecular weight of 240,000 per enzyme site^{16,17}. All protein determinations were carried out using a Biuret method¹⁸.

*P = 0.01.
**P = 0.005.
***P = 0.001.

compensation is controversial¹. In the case of activation energy (E_a), as calculated from Arrhenius' equation, a correlation exists with habitat temperature for some enzymes^{2,5,6} but not others³. Studies of activation energy are principally concerned with the enthalpy of activation (ΔH[‡]). There have been comparatively few studies of the free energy of activation (ΔG[‡]) between homologous enzymes from animals of different thermal environments^{7,8}. Low *et al.*⁸ showed a correlation between ΔG[‡] for muscle type (M₄) lactate dehydrogenase and body temperature. The relative importance of enthalpic (ΔH[‡]) and entropic (ΔS[‡]) activation between poikilotherms and homeotherms was also shown to be different⁸. Similar results have been obtained for skeletal muscle myofibrillar ATPase activity⁷. Since these studies deal with homologous enzymes from animals with very different phylogenetic positions it is difficult to assess directly the adaptive significance of changes in the magnitude of these parameters.

We have determined thermodynamic activation parameters for the Mg²⁺-activated myofibrillar ATPase of the white muscle of teleost fish inhabiting a wide range of thermal environments from Antarctic to tropical waters.

A plot of log₁₀V_{max} against the reciprocal of the absolute temperature (K) is called an Arrhenius plot. Arrhenius plots for myofibrillar ATPase activity show a discontinuity at 18.5 °C (ref. 7). This effect has been attributed to the binding of Ca²⁺ to troponin A in systems containing the intact calcium-sensitising system, since it does not seem to be observed with pure myosin in the presence of high levels of Ca²⁺ or with desensitised actomyosin preparations⁹. In the case of some species of fish, myofibrillar ATPase activity also undergoes an initial activation before denaturation at higher temperatures^{6,10}. This initial activation effect makes accurate determinations of native specific activity very difficult¹¹. Although the occurrence of this initial activation varies considerably between species (occurring at lower temperatures in cold-adapted species⁹) it is not observed in any of the species studied at temperatures below 25 °C. To overcome these complications, we have considered only the temperature range 0–18 °C. The method of calculating the thermodynamic parameters,

ΔH[‡], ΔS[‡] and ΔG[‡] from the corresponding Arrhenius plots and V_{max} determinations is given in the legend to Table 1.

Values of ΔG[‡], the free energy of activation of the reaction, were broadly similar for all species studied. The values obtained for the Antarctic fish *Nothenia rossii*, however, were some 800 calorie mol⁻¹ lower than those of species living at the highest environmental temperature (Table 1). Small differences in ΔG[‡] between homeotherms and poikilotherms have been noted both for myofibrillar ATPase⁷ and M₄ type muscle lactate dehydrogenase, D-glyceraldehyde-3-phosphate dehydrogenase and muscle glycogen phosphorylase b⁸, and may be of some adaptive significance. Table 1 shows that a more important feature of temperature adaptation in this enzyme concerns the relative contributions of enthalpic and entropic activation. While ΔG[‡] was relatively constant between species the proportions of ΔH[‡] and ΔS[‡] varied considerably. A positive relationship between entropy of activation and environmental temperature was demonstrated. Values of ΔS[‡] varied from large negative values for the cold-adapted species to high positive values for the tropical species. Similar differences have been found between the entropy terms of the myofibrillar ATPase from birds and mammals where entropy was high and positive relative to amphibians and reptiles, where the values were low or negative⁷. There was also a strong positive correlation between enthalpy of activation and the mean annual habitat temperature of the species. Values for ΔH[‡] varied from 6,850 calorie mol⁻¹ for the Antarctic species (*Nothenia rossii*) (mean water temperature 0–2 °C) to 33,000 calorie mol⁻¹ for a species from an equatorial hot springs soda lake, *Tilapia grahami* (35–38 °C). Both enthalpies and entropies of activation were fairly independent of assay temperature.

A compensation plot¹⁹ of entropy change (ΔS[‡]) against enthalpy change (ΔH[‡]) for the different species was highly linear ($P < 0.001$) (Fig. 1). The slope of this plot has the dimensions of K and is called a proportionality constant or compensation temperature¹⁹. Our values of 280 and 300 K for assay temperatures 0.5 and 18 °C respectively are in the range reported for similar plots for a wide range of protein

Fig. 1 The relationship between the enthalpy of activation and the entropy of activation for a range of species of fish living at different environmental temperatures.

reactions¹⁹⁻²². Examples include the binding of oxygen to vertebrate haemoglobin²⁰ and the formation of methaemoglobins for several mammalian species^{21,22}. The existence of a similar relationship between entropy change and enthalpy change, yielding similar compensation temperatures, for various processes of small solutes in water solution, has led some authors to implicate the participation of liquid water in these protein reactions^{19,20}. At present it is not clear whether the linear compensation patterns of these and other protein reactions are attributable to some general feature of protein-water interactions or arise entirely from some properties of the protein molecules themselves. If such compensation behaviour was found to indicate a general water-based phenomenon in protein reactions, this would have considerable biological importance in providing a theoretical framework both for the study of specific physiological processes and in the elucidation of mechanisms of molecular evolution.

Certainly, compensation behaviour of this type seems to provide biologically useful adjustments in the activation entropies and enthalpies for poikilothermic enzymes. The observed changes in ΔH^\ddagger and ΔS^\ddagger for myofibrillar ATPase, both of which increase from cold water to tropical habitats, are reflected in corresponding changes in the heat and entropy content of the muscle cells. Fish living at the higher environmental temperatures, where enthalpic activation is presumably facilitated, show a larger contribution of the enthalpic activation component. At low habitat temperatures, however, where enthalpic activation is likely to be energetically more unfavourable, the enthalpic component is partially replaced by a larger entropic contribution to the free energy of activation (Table 1). This has the advantage of greatly reducing the temperature sensitivity of the rate-limiting step in forming the activated enzyme-substrate complex. It might be expected that this would give significant adaptive advantage both to species which experience large fluctuations in environmental temperature and to those living in cold and temperate waters, since the limitations of the low heat content of the cellular environment have been partly offset.

It is known that myosins isolated from cold water species are characterised by a ready formation of aggregated products, within a few hours of preparation, and a concomitant decline of ATPase activity to zero²³. Such preparations are also more

easily denatured by urea and heat than the corresponding myosins from homoeotherms²⁴. It seems therefore that the concomitant structural adaptations in the tertiary structure of fish myosins consistent with their evolutionary modification for a low enthalpy environment necessarily make the molecule unstable at higher temperatures. Indeed a striking relationship has been shown between the thermostability of fish myofibrillar ATPase activity and the environmental temperature at which the species lives²⁵. The general order of thermal denaturation for this enzyme at 37 °C from 22 species of fish has been shown to be African equatorial lakes > Indian Ocean > Mediterranean > North Sea > Antarctic^{6,25}. The approximate half life of inactivation of the enzyme in comparable conditions varied some 350 times between these two temperature extremes. Species adapted to tropical environments presumably need a more rigid molecular structure to confer thermal stability at the higher environmental temperatures. Somewhat less marked correlations between thermostability and thermal environment have been shown for several mitochondrial enzymes in teleosts²⁶.

In view of the relevance of studies of myofibrillar ATPase to an understanding of muscle contraction, the molecular mechanisms of temperature compensation among this group of proteins seem to be of particular interest. A more detailed account of these phenomena will be presented later.

I.A.J. thanks the Natural Environment Research Council for a postdoctoral fellowship award and Professor G. M. Hughes for facilities. We thank N. J. Walesby and the British Antarctic Survey for specimens of *Notothenia rossii*. While this research was being carried out G. G. was in receipt of a grant from the Science Research Council.

C₄ photosynthesis in plants from cool temperate regions, with particular reference to *Spartina townsendii*

GREEN plants may be divided into two groups, C₃ and C₄ species, depending on whether the first product of photosynthetic CO₂ fixation is phosphoglycerate (C₃) or oxaloacetate (C₄). In all species studied to date the C₄ metabolism is associated

with either 'Kranz' leaf anatomy, low CO_2 compensation points or low $^{13}\text{C}/^{12}\text{C}$ ratios. Included in the C_4 category are many of the highest yielding and rapidly growing crops, most of which are believed to have originated in tropical and subtropical regions. C_4 species so far studied, which are mostly of tropical origin, attain their highest photosynthetic rates at leaf temperatures of about 30°C and above^{1,2} so that selective advantages derived from photosynthetic rate will only be evident in tropical and subtropical regions^{1,2}. A recent compilation of the reported rates of photosynthesis and productivity of C_3 and C_4 crops³ showed that differences in maximum annual dry matter yields could be explained by differences in lengths of growing season. It thus remains to be shown that there is a selective advantage which is a direct consequence of photosynthetic capacity of C_4 species or that there is an inherent physiological barrier to the adaptation of C_4 species to a similar range of latitudes to C_3 species.

There are two indirect consequences of C_4 photosynthesis which could be advantageous to plants irrespective of the climate in their region of origin. First, the ratio of weights of CO_2 assimilated to water transpired (the water-use efficiency) of C_4 plants, which is often twice that of C_3 species⁴, will be advantageous in habitats where water supply is limiting for growth or survival. Second, tolerance of salinity is a conspicuous attribute of many C_4 species. Indeed sodium is an essential micronutrient specific to C_4 species⁵ and may increase the *in vivo* activity of the primary carboxylating enzyme of C_4 photosynthesis, phos-

Fig. 1 Transverse section of a leaf of *Spartina townsendii* $\times 740$. The material was fixed in glutaraldehyde and post fixed in osmium tetroxide; after dehydration in ethanol, it was embedded in Epon and 1- μm sections cut for light microscopy²⁸. This section was stained with Toluidine blue and mounted in immersion oil. X, Bundle sheath cell containing chloroplasts. ('Kranz', the German word for wreath, was first used by Haberlandt⁷ to describe two concentric layers of chlorenchymatous tissues round the vascular bundles, the inner being the bundle sheath which contains chloroplasts, distinct from those of the outer mesophyll.)

Fig. 2 Mean \pm s.e. of CO_2 compensation point for leaves of *Spartina townsendii* at nine leaf temperatures and photon flux density of about $200 \text{ nmol cm}^{-2} \text{ s}^{-1}$. The compensation points were determined using an infrared gas analyser (Analytical Development, Series 225) in a simple closed-circuit system. The analyser was calibrated in the range $0\text{--}100 \text{ ng cm}^{-3}$ using mixtures generated from pure N_2 and 1% CO_2 (Rank Precision Industries) with two gas mixing pumps (H. Wösthoff) in series. The concentration of the 1% standard was checked against mixtures generated from pure CO_2 and pure N_2 , and cross-checked by conductivity analysis²⁹. In practice it was found possible to discriminate differences of less than 0.2 ng cm^{-3} over this calibration range. Photon flux density at the leaf surface was determined using a Quantum sensor (Lambda Instruments)³⁰. Leaf temperature was determined with a copper-constantan thermocouple junction (diameter 0.1 mm) tightly appressed to the lower surface of the leaf.

phenol-pyruvate carboxylase⁶. We therefore searched for temperate C_4 species in physiologically dry and saline habitats.

Three out of thirty common higher plant species, collected from coastal sand dunes and salt marshes around the coast of Britain, were found to have the 'Kranz' leaf anatomy associated with C_4 photosynthesis: *Salsola kali* L., *Atriplex lacinata* L., and *Spartina townsendii* (*sensu lato*). *S. kali* has previously been noted to be a C_4 species⁸. *A. lacinata* and *S. kali* occur as far north as Sweden and are locally abundant at many sites around the British coast. *S. townsendii* is exceptional among the C_4 species now known to be native or introduced to Britain, in that it is a dominant component of large areas of our coastal salt marshes⁹.

Previous studies of *S. townsendii* have reported the bundle sheath to consist of large colourless cells^{10,11}, or only to contain chlorophyll in young plants¹². All material examined in populations from Southampton Water, the Ribble Estuary, and the Humber Estuary, however, showed 'Kranz' leaf anatomy (Fig. 1). In all cases the large bundle sheath cells contained numerous chloroplasts, often adjacent to the outer wall. Only the chloroplasts of the bundle sheath accumulated starch; they also differed in having twice the cross-sectional area and grana with fewer thylakoid stacks. All of these differences between chloroplasts have been found to a greater or lesser extent in the leaves of other C_4 species¹³, and clearly establish the occurrence of 'Kranz' anatomy in *S. townsendii*.

To test the anatomical inference that *S. townsendii* is a C_4 species we determined the CO_2 compensation point—that is the CO_2 concentration in air at which the net flux of CO_2 at the leaf surface in the light is zero. This is usually within the range $0\text{--}20 \text{ ng cm}^{-3}$ for C_4 species and $60\text{--}140 \text{ ng cm}^{-3}$ for C_3 species. The mean CO_2 compensation point for *S. townsendii* does not exceed 10 ng cm^{-3} over the range of leaf temperature $5\text{--}40^\circ\text{C}$ (Fig. 2) which confirms the occurrence of C_4 photosynthesis.

Fig. 3 Mean \pm s.e. of response of leaf photosynthetic rate at a photon flux density of about $200 \text{ nmol cm}^{-2} \text{ s}^{-1}$, to leaf temperature for *S. townsendii* (▲) compared with data obtained by others for three other grass species. Plants of *S. townsendii* collected from the Humber Estuary were grown in a controlled-environment cabinet (CM94PG, Fisons) at day-night air temperatures of 16/13 °C, a vapour pressure deficit of about 0.5 kPa and a photon flux density during the 16-h day of $50 \text{ nmol cm}^{-2} \text{ s}^{-1}$ at the crop surface. Nutrient solution (200 ml) (Solu-feed, ICI) was added to each 15-cm diameter plant pot once every 3 weeks. Steady-state leaf photosynthetic rate was determined in an open-circuit gas exchange system. A glass water-jacketed, air-sealed, leaf chamber was used to provide accurate environmental control over single attached leaves. The light source was a high pressure sodium lamp (SON/T 400W, Philips) with a parabolic reflector. Photon flux density and leaf temperature were measured as described in Fig. 2. Ambient CO_2 concentration in the air supplied to the leaf was maintained at 600 ng cm^{-3} , and the water vapour pressure deficit at 0.3 kPa. The net flux of CO_2 at the leaf was determined by differential gas analysis. The infrared gas analyser was calibrated by the split-tube method of Parkinson and Legg³¹ using gas mixtures generated by the method described in Fig. 2. Growth of material and measurement of photosynthesis and microclimate for *Sesleria albicans* (▽; ref. 15), *Festuca arundinacea* cv. S170 (□; ref. 16) and *Pennisetum purpureum* cv. 05088 (○; ref. 14) was by similar methods to those described here.

Although many C_4 species may attain leaf photosynthetic rates often three times those of C_3 species, these differences are only realised at relatively high temperatures. The C_4 species, *Pennisetum purpureum*, is reputed³ to be the world's highest yielding forage crop. At 38 °C its rate of leaf photosynthesis¹⁴ is some three times the maximum obtained by two temperate C_3 grasses *Sesleria albicans*¹⁵ and *Festuca arundinacea*¹⁶ (Fig. 3). At 16 °C, however, the mean air temperature for the warmest month in South-east Britain, its rate is lower than that obtained by the C_3 grasses. In common with other C_4 grasses, photosynthesis in *P. purpureum* ceases at leaf temperatures of 7 °C and below, whereas *S. townsendii* maintains significant photosynthetic rates at 5 °C (Fig. 3) and rates at relatively low temperatures, 5–10 °C, comparable with C_3 grasses (Fig. 3). The leaf photosynthetic rate of *S. townsendii* at 25 °C is about 50% higher than the maximum rates reported for the major herbage grasses of Britain¹⁷. Its temperature optimum for photosynthesis (30 °C) however, is 7–11° lower than optima for other C_4 grasses, measured in similar conditions^{14,18,19}. Net

photosynthetic rate in *S. townsendii* declines with increase in temperature above 30 °C, so that at 40 °C it is 10% of the rate at 30 °C. This does not result from the occurrence of photorespiration at these temperatures, because the compensation points from 30–40 °C do not differ significantly from those at lower leaf temperatures (Fig. 2).

S. townsendii is considered to have arisen from the hybridisation of *S. maritima* (Curt.) Fernald, endemic to Europe and Africa, and *S. alterniflora* Lois., a species introduced from North America²⁰. *S. alterniflora* is one of five species of the genus *Spartina* native to North America which have previously been suggested to be C_4 (refs 21–25). *S. maritima* (Mersea Island, England) possessed typical 'Kranz' leaf anatomy. Since its first recorded appearance at Southampton Water in 1870, *S. townsendii* has spread, both by natural dispersal and by deliberate plantings, to occupy over 12,000 hectares of intertidal mudflats around the British Isles. Attempts to introduce *S. townsendii* to latitudes below 48 °N have repeatedly failed, but it has been successfully introduced to Udale Bay, Scotland (57.5 °N), and to salt marshes in Denmark where it now occupies over 500 hectares (ref. 26). This pattern of distribution suggests that *S. townsendii* is a plant limited to cool temperate regions and thus affords an unrivalled opportunity to examine the potential of C_4 photosynthesis in these conditions.

It is of interest that the perennial *Spartina gracilis* Trin., an inland North American species, which has a distribution extending to above 60 °N into the North West Territories of Canada²⁷, also has 'Kranz' leaf anatomy.

In conclusion, *S. townsendii* is a C_4 species adapted and limited in distribution to cool temperate climatic regions. One feature of this adaptation is the ability of the species to maintain significant rates of photosynthesis at relatively low temperatures, which contrasts with observations on other C_4 grasses. Thus, C_4 photosynthesis is not inherently limited to subtropical and tropical regions and physiological adaptation of this process to a cool temperate habitat has occurred.

X-ray evidence of temperature-dependent conformational disorder of hydrogen-bonded carboxylic acid molecules in crystal structures

FROM an analysis of X-ray data on carboxylic acids¹ we have established the stability of the approximately coplanar arrangement of the non-hydrogen atoms of the acetic acid group (C-COOH) with the α substituent in α -substituted carboxylic acids (Fig. 1). In the crystal structures of tartaric acid (X = OH) (ref. 2), aminomalonic acid (X = NH₂) (ref. 3) and fluoroacetic acid (X = F) (ref. 4) the coplanar *cis* conformation has been found. In crystals of unsubstituted monocarboxylic acids the acetic acid group has been found to be coplanar with the β -carbon atom¹.

Fig. 1 *Trans* (a) and *cis* conformation (b) in α -substituted carboxylic acids.

From infrared studies of unsubstituted monocarboxylic acids at different temperatures, Hayashi *et al.*^{5,6} deduced that in odd-numbered acids the crystal contains the *cis* form at lower temperatures, whereas (lower members excepted) crystals of the even-numbered acids contain the *trans* form. As yet, X-ray evidence to support these conclusions is scarce⁷⁻⁹. Hayashi also pointed out that by assuming the difference in energy between the *cis* and *trans* forms to be small, it may be expected that they coexist in crystals of carboxylic acids in various temperature-dependent statistical proportions.

A feature common to the crystal structures of carboxylic acids is that the carboxyl groups predominantly couple with one another to form the well known eight-membered rings. A transition from the *trans* to the *cis* form or *vice versa* may be conceived of as a simultaneous transport of the protons along the hydrogen bond, accompanied by a rearrangement of the electron density and subsequent changes of bond geometry in the various carbon-oxygen bonds, packing considerations ruling out the mechanism involving a rotation of the carboxyl groups (Fig. 2). The assumed coexistence of the *trans* conformation and that of *cis* in different ratios in crystals will imply that in the X-ray analysis C-O bond lengths and C-C-O bond angles are found that are weighted averages of C=O and C-O lengths and C-C-O and C-C=O angles, respectively.

This variation in the carboxyl group geometry is, as far as bond lengths go, subject to the Speakman rule¹⁰, which states that the sum of the carbon-oxygen distances will be 2.52 ± 0.02 Å. For example, at room temperature (RT) C-O bond lengths in benzoic acid¹¹ are 1.24 and 1.29 Å, whereas in tartaric acid² these distances are 1.21 and 1.30 Å.

It is in the RT structure of fluoromalonic acid¹², where C-O lengths and C-C-O angles are equal within experimental error (Table 1), that this supposed *cis-trans* disordering must be at its maximum. The expectation that such a disorder would split

Fig. 2 *Cis-trans* transition by proton transfer in a cyclic carboxylic acid dimer configuration.

the hydrogen atom electron density along the hydrogen bond donor-acceptor line, we found to be true in a subsequent, more accurate redetermination of the crystal structure of fluoromalonic acid (Fig. 3a). Hayashi's concept of temperature-dependent disordering in crystals of organic acids prompted us to look into the change in carboxyl group geometry at liquid nitrogen temperature (LNT) in crystalline fluoromalonic acid. As this acid constitutes the ideal test case, a temperature decrease here dictates a drastic alteration of disordering.

X-ray results derived from data obtained from a single crystal of the highly hygroscopic acid, prepared by sublimation *in vacuo*, are summarised in Table 1. Cooling selectively reduces the length of the *b* axis by about 0.4 Å, whereas the *c* axis increases by about 0.09 Å. The carboxyl group geometry tends to be similar to that of a 'normal' carboxyl group. The hydrogen atom electron density splitting has disappeared and

Fig. 3 Electron density difference synthesis in the plane of the carboxyl group dimer. Contours on an arbitrary scale. a, RT; b, LNT.

Table 1 Summary of X-ray crystal structure analysis of fluoromalonic acid at RT and LNT

	RT	LNT

Hydrogen bond: O(1)–O(2')	2.657(2) \AA	2.649(2) \AA
('') = 1 – x, – y, – z.		

an asymmetric single maximum is now found in the electron-density difference map (Fig. 3b). As the molecule at LNT clearly has the *trans* form, the question arises as to whether the established *cis* stability at RT in crystals of α -hydroxyacids and of fluoroacetic acid also applies to these structures at LNT.

The results for fluoromalonic acid give the first unambiguous X-ray evidence of conformational disorder at elevated temperatures in molecular crystals of carboxylic acids. Note that the RT X-ray analysis of the crystal in question after the LNT experiment again shows the same geometrical anomalies, which can now definitely be ascribed to conformational disorder.

We thank Dr Hayashi for making available his results before publication.

Errata

In the article "The modulation contrast microscope" by R. Hoffmann and L. Gross (*Nature*, **254**, 586, 1975) equation (1) should have read

$$U_{(0)} \sim \int e^{-i\phi x} e^{-i\theta x} dx$$

and not as printed.

In the article "Localisation of human peptidase-A structural locus from studies on a cultured lymphoblastoid line" by E. Arthur, C. M. Steel, H. J. Evans, S. Povey, B. Watson and H. Harris (*Nature*, **257**, 308; 1975) the legends for Figs 2 and 3 were transposed. The figures are correct as they stand.

Corrigendum

In the article "A resonant point absorber of ocean-wave power" by K. Budal and J. Falnes (*Nature*, **256**, 478; 1975) the absorption length $d_a = P_{\text{opt}}/K$ was estimated to be $d_a = 50$ m in small-amplitude sinusoidal waves and $d_a = 20$ m in real North Atlantic waves when the tank diameter is $2a = 16$ m. This result was based on the approximation that diffraction effects are negligible when $a \ll \lambda$ where λ is the wavelength. Unfortunately, this approximation overestimates d_a when a is as large as 8 m. Including diffraction effects in the calculation it is found that the absorption length in small-amplitude sinusoidal waves is $d_a = \lambda/2\pi$, irrespective of the value of a . This result is valid for any circularly symmetrical, optimised, resonance-tuned heaving body on deep water. In small-amplitude sinusoidal waves of period $T = 10$ s this gives $d_a = 25$ m instead of $d_a = 50$ m. In the case of wind-generated waves the overestimation of d_a is less drastic. The general conclusions drawn regarding the advantage of point absorbers are still valid.

New and Recent Publications in Obstetrics, Gynecology and Reproductive Biology

Aspects of Obstetrics Today

edited by T. K. A. B. ESKEs, J. DE HAAN,
H. VAN KESSEL and J. G. STOLK.

1975 464 pages US\$ 61.75 / Dfl. 148.00
ISBN 90-219-2083-0

This volume reviews research activities in the field of obstetrics, gynecology and reproductive biology conducted under the guidance of Professor L. A. M. Stolte in The Netherlands. The contributors to this volume review the most recent concepts and modern techniques in obstetrical care and cytogenetics.

Human Placentation

Proceedings of an International Symposium,
29-30 July 1974, Leuven, Belgium

edited by I. BROSENS, G. DIXON and
W. B. ROBERTSON.

Reprinted from the *European Journal of Obstetrics,
Gynecology and Reproductive Biology*,
Vol. 5, No. 1/2

1975 184 pages US\$ 28.50 / Dfl. 68.00
ISBN 90-219-2092-1

The main topics of this symposium were related to the structure and function of the placenta, to the evaluation and treatment of some of its insufficiencies, and to the immunology of the normal and abnormal pregnancy. Research workers in clinical obstetrics, perinatology, reproductive biology, immunology, endocrinology and related disciplines presented cogent papers which were followed by informal discussions.

reviews

OVER the last decade the quest for a semantics of natural language has reached the proportions of an intellectual's crusade. Dedicated regiments of linguists, logicians, psychologists, and computer scientists, have set off for the Holy Land, and massive amounts of intelligence, both real and artificial, have been directed at what turns out to be a most intractable infidel. There have been a few piecemeal victories, but the campaign so far has been a failure. There is no single hypothesis that provides a convincing and general theory of what meaning is.

Walter Kintsch's book offers us a psychologist's view of the battleground, and it illustrates many of the strengths and most of the weaknesses of this perspective. Kintsch believes that the essential strategy is to find the right notation. He represents the meaning of a sentence such as, "Peter put the book on the table", by the formula: (PUT, AGENT: PETER, OBJECT: BOOK, GOAL: TABLE).

That is all very well, but what is the notation for; what does it do? Kintsch does not tell us. Nor does he tell us precisely what he means by AGENT, OBJECT, or GOAL. Indeed, one of the great drawbacks of these notions, which derive from Fillmore's 'case' grammar, is that no one has ever succeeded in stipulating a meaning for them that is wholly explicit and that requires no exercise of intuition on the part of the reader. The trouble with doing semantics by translating an expression from one language into another is that one needs a semantics for the 'meta'-language. Kintsch does not provide one, and so it is singularly unsatisfying to learn that the meaning of 'put' is 'PUT'. But at least at this point we reach a current controversy.

GOAL: MEANING

P. N. Johnson-Laird

The Representation of Meaning in Memory. (The Experimental Psychology Series.) By Walter Kintsch. Pp. vii+279. (Lawrence Erlbaum: Hillsdale, New Jersey, 1974.) £8.00.

Everyone agrees that the meanings of many words can be decomposed into more basic constituents: 'kill' can be analysed, for example, as 'cause to become not alive'. The question is: should this analysis be part of the meaning of the word as it is represented in the mental dictionary, or should it be captured by rules ('meaning postulates' as Carnap originally dubbed them in another context) for interrelating different expressions in the language? In a variety of experimental manipulations, Kintsch failed to find any evidence for an actual decomposition into more primitive elements, and he accordingly rejects the notion of analytical dictionary entries in favour of meaning postulates. There seems to be little reason to accept this conclusion.

Analytical entries may well exist, but may only be consulted in certain circumstances as, for example, when a speaker attempts to define a word, or a listener attempts to verify a sentence. Indeed, it is hard to know what empirical data would in principle decide the issue. A further problem with rules which merely relate expressions is, of course, that they provide no way of relating language to the world, no way of determining the truth or falsity of an assertion. Kintsch's theory does not

even attempt this task, not does it offer any systematic account of meaning postulates. It is a semantics without any semantics.

The one idea that does emerge from the theory is that sentences, or at least assertions, express underlying propositions. A sentence such as, "The fire destroyed many acres of virgin forest", contains four underlying propositions: (DESTROY, FIRE, FOREST); (SIZE, FOREST, ACRE); (VIRGIN, FOREST); and (MANY, ACRE). The notation presents numerous logical problems, but fortunately nothing crucial hangs upon it. Kintsch is able to predict a variety of aspects of the processing of prose simply on the basis of the number of propositions, and their gross interrelationships, that are expressed in it.

The content of the book changes abruptly in calibre in its second half, which is devoted largely to an account of a series of original experiments concerning the reading, representation, and recall, of paragraphs. This research is a sustained and sometimes ingenious attack on an intriguing psychological problem.

One final warning. This book is suitable reading only for psychologists. Logicians will be repelled by its logical inadequacies. Linguists will find little new in it. Computer scientists will be deterred by its failure to grapple with the function of a semantic theory. Psychologists, however, will find in it some stimulating experiments, written up in the detailed style of journal articles. They may also gawp at the mathematical filigree—flashy, but perhaps irrelevant—with which the author fits model to data. Meanwhile, back in the Holy Land, Jerusalem remains unconquered. □

THERE are many books on bees but few on the end product of their labours. Most books on honey are in the realms of folk law and health foods. As a result this text by a distinguished group of international specialists backed by the resources of the Bee Research Association is a landmark.

Divided into five sections with sixteen chapters the content has a potential appeal to a wide readership. Sections 1 and 3 dealing with the production and preparation of honey will appeal to beekeepers. Section 4 deals with the commercial aspects and will interest those involved in international trade and legislation.

Section 2 is the major scientific contribution covering the chemical, physical and biological characteristics and is the first attempt to put the

Honey for some

Paul Wix

Honey: A Comprehensive Survey. Edited by Eva Crane. Pp. xvi+608. (Heinemann: London, 1975.) £15.00.

material into a book where it can relate to wider issues. Section 5 has its appeal for those interested in the history and language associated with honey.

The scientists will find detailed

treatments of the chemical, physical and microscopic (pollen analysis) data, and under the brief section on biological properties every attempt has been made to separate fact from folk law. This represents a starting point for those who consider that honey still holds most of its biological secrets close-hidden.

The late 1600s woodcut with the Latin "So we the bees make honey, but not for ourselves" is a fitting tribute to the long association between man and bees. At £15 it is fairly priced although as a book of reference it might have been wise to have increased the price in favour of a paper with a finer finish. □

The Filament Fungi, Volume 1, *Industrial Mycology*. Edited by J. E. Smith and D. R. Berry. Pp. xii+340. (Edward Arnold: London, April 1975.) £12.50.

THIS is the first volume of a series devoted to the filamentous fungi and is intended to be used by senior undergraduate and postgraduate students as well as by workers involved in the pharmaceutical, chemical and food industries. The industrial applications of yeasts have been fully considered elsewhere and have not been included.

Twenty authors have contributed the sixteen chapters which constitute this volume. The backgrounds of these authors are somewhat different but it is of interest that all except four are at present working in Britain. Academics are more frequently represented than those engaged in work in industrial establishments.

No attempt is made to provide any treatment of the taxonomy of filamentous fungi or to provide assistance in their recognition. The first portion of the book deals with such fundamental aspects as structure and development, environmental control of physiology, secondary metabolism and its relationship to growth and development, strain improvement and stability and growth kinetics. The fungi are particularly prolific in the production of a wide range of secondary metabolites and since only a minority of species has so far been studied the real extent of the range of products they can produce is likely to be shown to be very much wider than is at present appreciated.

The second portion of the book deals mainly with the fungal fermentation industry. In an account of the historical development of this industry it is shown that the discovery of penicillin, followed by other antibiotics, provided the main initial impetus for the rapid expansion of the industry at a time when the background knowledge made such an expansion possible. After a discussion of commercially important secondary metabolites there are chapters dealing with the commercial production of organic acids, the transformation of organic compounds by fungus spores, industrial enzyme production, industrial exploitation of ergot fungi and oriental food fermentations. In a chapter entitled 'Submerged culture production of mycelial biomass' the modern developments in the production of protein by mycelial biomass and in the production of mycelium for use as flavouring agents are discussed. Three useful chapters on the cultivation of edible mushrooms, mycotoxins and biodeterioration and biodegradation by fungi are provided.

Not only does the text provide an up-

to-date and comprehensive treatment of the subject but the citation of a considerable number of publications at the end of each chapter is useful. The book is well produced although the few photographs are rather poorly reproduced. It represents a valuable review of an important field of study.

J. Colhoun

Mycogenetics: An Introduction to the General Genetics of Fungi. By J. H. Burnett. Pp. xiv+375. (Wiley: London and New York, 1975.) £12.50, cloth; £6.00, paper.

THIS work gives wide coverage to all the significant aspects of fungal genetics, and comprises four sections: structure and life histories of the various groups of fungi; formal genetics (genetic markers, linkage and recombination in

Fungi

meiotic and mitotic systems, extra-chromosomal elements and quantitative inheritance); population genetics (variation, selection and isolating mechanisms); industrial applications; genetics of fungal pathogenicity; and the mechanism of recombination and of gene action and regulation in fungi. Although there are no photographic plates, the text is admirably illustrated with numerous diagrams, figures, line drawings, tables and graphs. Worked examples are included and should prove valuable in understanding the complexities of, for example, the analysis of unordered tetrads and of certain aspects of quantitative inheritance.

The text is not easily read because of the extreme condensation of research publications, the profusion of technical terms and frequent directions to refer backwards or forwards to chapters or illustrations. There is also the interpolation of numerous references to original work. The introductory reader must be prepared to cope with the 'jargon' liberally sprinkling the text, as no glossary of these perplexing terms is given. Indeed, a few of the terms are not even defined in the text: for example, introgression, allopatric and sympatric.

The author must be taken to task on a number of points where I feel important omissions, ambiguities or even errors have been made. For instance, in the legend to Figure 5.4 it is mentioned that 43 out of 120 *trp-1* mutants of *Neurospora crassa* show no complementation with each other or with any of the mutants which fall into the eight complementation groups. The significance of such non-complementing mutants is not considered.

In the analysis of ordered tetrads, the

author states that the centromere distance of a locus is half the percentage frequency of second-division segregation asci for that locus because "a single cross over involves two of the four chromatids, that is, half of them". In fact, in higher diploid organisms the map unit was based directly on recombination percentage which represents the percentage frequency of "half chiasmata". In a second-division ascus, a whole reciprocal chiasma has been detected and so the percentage frequency of second-division asci is divided by two to give the centromere distance in conventional map units. The author then states that double cross overs between the locus and the centromere will be recorded as first-division segregations. This is not true because a three-strand double cross over will be recorded as a second-division ascus, as if a single cross over had occurred. The author attributes this "reduction in the real incidence of recorded cross over" to account for a maximum value of 67% second-division asci. This statement is somewhat ambiguous.

In the explanation of hybrid DNA formation during recombination between two of the four chromatids with the resulting formation of mis-matched base pairs, the author states, "Any mis-matched base pairs in the 'hybrid DNA' region are then corrected". He fails to realise that sometimes none of the mis-matched base pairs may be corrected so that no gene conversion occurs but post-meiotic segregation leads to the formation of "aberrant 4+:4m asci", with 'misplaced' spores, but in which the outside markers show normal 4+:4m segregations. Such asci are not mentioned yet they provided the key to the understanding of gene conversion. Consequently the author is, as it were, one step out in the subsequent possibilities.

Finally, the author does not mention valuable work and models proposed by Professor Olive and coworkers or the still more recent work by various researchers.

Those aspects of fungal genetics with which the author is familiar and to which he has contributed by original research, are treated in a full, interesting and up-to-date manner. To be fair to the author, he does state in the preface that he has tried to concentrate on general issues rather than to report the latest findings on any particular topic, but this method is likely to result in uneven treatment of the various aspects. He tells us also in the preface that the book is intended not only for geneticists but also for mycologists, pathologists, industrial users of fungi and biologists. I fear, however, that most of the latter types of reader will find the text turgid and tough going.

L. C. Frost

Computer checks . . .

Computer Chess. (ACM Monograph Series.) By Monroe Newborn. Pp. xii+200. (Academic: New York and London, April 1975.) \$15.00; £7.20.

1975 SEES the 25th anniversary of Claude Shannon's *Programming a Digital Computer for Playing Chess* (*Phil. Mag.*, 41, 356; 1950), and it is an appropriate time for a review of the developments which have occurred in this field since the appearance of that classical paper.

The better computer programs in the US and USSR are now achieving standards of play which make them interesting, not only to the computer scientist, but also to the chessplayer, for, in the games of computers, the chessplayer can recognise patterns of play which are familiar among human chessplayers. Indeed, for me, a principal fascination of this book arises from the existence in computer games of traits which I would, in human players, regard as personal styles, and yet which are, in the computer, seen to be consequences of simple arithmetical processes. This is not to imply, however, that the computers have yet reached human capability, even on the chessboard, for the absence of that indefinable human quality known as 'common sense' is all too evident in the computers' deliberations. That absence is perhaps the outstanding feature of all computer chess, and makes it unmistakably different from the human variety, for, unlike the human player of comparable ability, the computer will often engage in study of local minutiae, while obvious catastrophe threatens in another sector. Examples of this amusing behaviour are frequent in the book, and will reassure the reader who fears that his mind may soon be superseded.

The full appreciation of this book requires from the reader a moderate knowledge of chess. Fortunately, there is no corresponding requirement regarding a familiarity with computer programs. Thus, in my view, the other principal success of the book lies in its presentation of the structure and mechanics of computer chess programs in a manner which is not subject to obscurity by computer software jargon. Using simple language, the author presents a short, general survey of the techniques common to most chessplaying systems, and he includes a more detailed description of one of his own, quite successful, programs.

The central part of the book consists of some 36 analysed computer games. In the analysis, both the situation as interpreted by a competent chessplayer, and the rather different interpretations made by the computers, are presented in parallel as the games proceed. The games are taken principally from American intercomputer tournaments,

and cover the period 1967-74, thus enabling the reader to assess the progress, up to quite recent times, of this rapidly evolving art.

Overall, I would say that this book represents a successful navigation of the straits between the Charybdis of obsolete tedium and the Scylla of trivial immediacy which flank this rapidly developing subject.

Nigel J. Holloway

. . . into the past

Mathematics and Computers in Archaeology. By J. E. Doran and F. R. Hodson. Pp. xi+381. (Edinburgh University Press: Edinburgh, 1975). n.p.

FEW, if any, archaeologists now hold the view that 'science' has no place in archaeology, and in recent years mathematics and computing have become increasingly recognised as indispensable archaeological aids. The authors of this book rightly criticise some previous workers who have attempted to become 'scientific' by seizing on fashionable theories and forcing archaeological data into them, with a concomitant naïve and empirical use of borrowed 'hypothetico-deductive' jargon. This is an eminently readable book, refreshingly free from such jargon, which is intended for the archaeologist with no specialised mathematical knowledge, and which serves as an introduction to the subject, a critical summary of previous work, and an invaluable reference manual. It is written with simplicity but without condescension, the style being marred only by frequent confusion over the use of the first and third person and by an unnecessary proliferation of exclamation marks.

In Part 1, which deals with basic archaeological and mathematical tools,

care is taken to explain fundamentals such as algorithms, vectors and functions, in terms quite comprehensible to the intelligent innumerate. Simple examples are chosen to illustrate such concepts as probability, and there is an excellent section on sampling and significance testing.

Part 2, which is devoted to data analysis techniques, presents a number of ways of dealing with the regularly recurring archaeological problem of classifying great masses of highly complex items. Reasoned, if caustic, arguments are levelled against much of the mythology of the 'New Archaeology', and at the many invalid approaches to taxonomy which have been used in the past with only partial understanding of the numerical methods involved. The section closes with a useful series of examples of data analyses, including Hodson's comparative taxonomy and seriation of the Münsingen La Tenè fibulae.

Part 3, which is concerned with problems and prospects for the future, includes especially helpful sections on automatic seriation techniques and the use of computer-based archaeological data banks.

This is a volume to be thoroughly recommended, both as an introduction to first principles and as a practical comparison of the different techniques, including an assessment of their theoretical value. The general presentation of the book is of a high standard, but suffers from occasional erratic spacing and printing, together with poor reproduction of some of the simpler sketch-diagrams. At £8.00 for nearly 400 pages it is expensive but not overpriced, and it will undoubtedly remain the standard introduction to the subject for several years to come. M. L. Shackley

Solar one, a solar electric home built by the University of Delaware. From *Energy Resources*. By Andrew L. Simon. Pp. x+165. (Pergamon: Oxford and New York, 1975.) £6.40, \$15.00, boards; £3.40, \$8.00, paper.

Synaptology

Synapses and Synaptosomes: Morphological aspects. By D. G. Jones. Pp. xiv+258. (Chapman and Hall: London, July 1975; distributed in the US by Halstead.) £14.40.

THE demonstration by Whittaker and by De Robertis in the early sixties that nerve terminals carrying synaptic complexes can be isolated in enriched fractions after controlled tissue rupture, initiated a new approach for synaptology and caused an urgent reappraisal of the nature and purity of subcellular fractions from brain tissue. Gareth Jones' monograph sets out to provide an up-to-date review of the current picture of knowledge on nerve terminals, synaptic complexes and their *in vitro* derivatives, the synaptosomes. Although the subtitle predicts a basically ultrastructural content, the text ignores this constraint and provides a biological overview of the synapse, dealing with the biochemical and physiological correlates of the observed morphology.

The final chapter gives in outline the continuing debate over the source of transmitter released in to the synaptic cleft, and deals with the vesicle hypothesis, exocytosis, and the current indications that contractile proteins may be involved in the mechanism. Another chapter describes in some detail the preparation of synaptosomes from the precise conditions of tissue rupture, the use of gradients of different types and compositions, and subfractionation of the synaptosome itself. The use of synaptosome-enriched fractions in the study of nerve terminal metabolism and of transmitter synthesis, storage and release constitutes a separate chapter. In particular it emphasises the awakening of neurochemists to the opportunities offered by the fact that synaptosomes are sealed structures, most likely generating membrane potentials and carrying a full complement of metabolic and transmitter-linked enzyme systems, fully capable of functioning in a controlled and integrated fashion for many hours *in vitro*. Moreover, they respond to depolarising stimuli with transmitter release.

The real strength and authority of the book, however, is in the two chapters on ultrastructure, reflecting the author's long association with synaptic morphology. He deals with the synapse *in situ* and the changes which may be seen in the derived synaptosome. There is a useful account of differential electron microscopic staining techniques for various synaptic constituents and components, using phosphotungstic acid, bismuth-

iodide-uranyl acetate or zinc iodide-osmium tetroxide mixtures. There is an appraisal of the ultrastructural status of an array of synaptic components including pre- and postsynaptic dense projections, coated (complex) vesicles, baskets, cytonets, reticulosomes, tetrasomes and other structures observed using new fixation, staining and other visualising methods.

The text is written in an interesting and vigorous style and is fully illustrated with copious line drawings and over 100 micrographs. It is a useful addition to the literature on synaptology and will no doubt find its way into most libraries of neurobiology provided the price is not too strong a deterrent.

H. F. Bradford

Chordate morphology

The Chordates. By R. McNeill Alexander. Pp.vi+480 (Cambridge University, April 1975.) Cloth £10.00 \$28.50; paper £4.25.

MORPHOLOGY is a dull subject, and there are only two good reasons for teaching it: either that the structures are important in the animal's way of life, or that they illuminate its evolution and relationships. But, in many universities, the systematic morphology section of zoology is now isolated in a separate course unit, divorced from the related physiological and ecological viewpoints which help to make it significant and interesting.

Those who teach such courses therefore have to find individual topics in which the importance of morphology is shown clearly, or in which its study can be used to exemplify the aims and methods of modern research. The adaptive significance of many of the gross morphological structures is clearly obvious, and is already described in many textbooks. But analyses of the mechanics of swimming or mastication, for example, have developed a great deal since most of the commonly-used textbooks of vertebrate biology were written. Alexander's book not only provides these up-to-date analyses, but also a similar range of examples of the ways in which vertebrate structures are physiologically adapted. He has succinctly set out his aims in the Preface:

"Most of the book is about animal structures, how they seem to have evolved and how they work. A great many experiments are described because it is often as interesting and worthwhile to know how an item of knowledge was obtained as to know the item itself. Since the book is about structures, many of the explanations involve physics or engineering. There are many simple calculations designed either to throw light on the dimensions of a structure, or to test the plausibility of an explanation.

There is information in this book about locomotion, respiration, blood circulation, feeding, osmotic and ionic regulation and sense organs. These topics relate well to gross structure."

Alexander has cast his net fairly widely. For example, some of the topics covered in the first 200 pages of the book are rates of water flow through gills and of gas diffusion into gills, the structure and mechanical properties of bone, the hydrodynamics of swimming, the mechanics of jaw and gill action, the physics and physiology of teleost swim-bladders, the optics of silvery reflective fish camouflage and the physiology of electric organs. Such topics are considered thoroughly and clearly, as relevant to the life of the group in question. They are dealt with at both the theoretical and the experimental level, and will help students to realise that morphology is really only a series of problems in adaptation, not all of which are, as yet, properly understood.

The book does not pretend to uniform coverage of the different chordate groups; 190 pages are devoted to fish, as against 230 for the remaining vertebrates. Criticism of this imbalance could fairly be countered by pointing out that it does not matter which group is used to illustrate a principle, as long as it is adequately illustrated. Also, since Alexander's research has been centred on fish, it is natural that he should turn to them for many of his examples. Nevertheless, it does mean that those of us whose sympathies have accompanied the tetrapods onto land will feel a little disappointed.

About half of the 214 figures were drawn especially for the book, and many of the remainder have been taken from research papers. Many will be new to those accustomed to more conventional textbooks of vertebrate morphology, for there are many figures of experimental apparatus, graphs and physiological recordings of different kinds. The diversity of sources has led to a variety of styles, and a few figures have reproduced poorly.

This book does provide a new and up-to-date functional approach and it is a valuable addition to the library of anyone designing a course in vertebrate zoology, or for students taking such a course (for whom there is a reasonably-priced paperback edition). Of course, this new approach has been at the expense of the conventional coverage of such topics as the adaptive radiation of the groups, or their relationships to one another or to geological periods and time. But for those of us who want it, this information is easily available in other books, and such omissions are a small price to pay for such a welcome, innovative book.

Are scientists really stifling science?

SCIENTISTS are stifling science; Professor John Taylor of King's College, London put this proposition to an audience at the Royal Institution in a televised "Controversy" programme this week. Within the necessary confines of a televised debate it is all too easy to judge the matter won or lost on style rather than content; Professor Taylor raises an important issue and it merits careful consideration within the scientific community.

There is, of course, a very specific circumstance surrounding Professor Taylor's unease. For the past two years he has been attempting to come to terms with a variety of phenomena that are usually put into the paranormal category. His motive has, he insists, consistently been to explain these phenomena by means of conventional scientific concepts. History is on his side in this respect; many phenomena which in the past were regarded as bizarre or supernatural have yielded to scientific analysis. History, as his critics continue to urge (see Professor Hammerton's letter on page 640), is not on his side in offering too much encouragement that professional scientists can outsmart professional deceivers, if deceivers some be.

The issue at hand, however, goes far beyond metal bending. Scientists are in an unusually favoured position in policing their profession, and so they have a special responsibility to keep these policing mechanisms up-to-date, fair and seen-to-be-fair. Governments devote vast sums of money annually to the practice of science, and even when the science is obviously directed at solving pressing problems, the scientist is still the ultimate arbiter of what he does and doesn't do. Indeed through a variety of mechanisms from refereeing for journals to sitting on grant-giving bodies, scientists are arbiters of what others are allowed to publicise and spend money on. Do scientists warrant the trust that the public, unwittingly, puts in them to keep their house in order and forward-looking?

The greatest guarantee that the uncommon or unusual idea will get some sort of hearing is pluralism. If the sources of money are not controlled by just one committee, if the means of publication are not all in the hands of one person, if education is not according to some unified syllabus, then the prospect of any one group of people being able to exert an unhealthy influence is vastly diminished. And those who cannot get satisfaction through normal channels can often be remarkably effective in unusual ways. Research does

not have to have been sponsored by the Science Research Council to be distinguished, nor does it have to be published in *Nature* to command wide attention. Indeed some of those who feel they are unjustly ignored might be surprised how well known and extensively thought about their work is; simply because no-one relishes the thought of being known to posterity as the person who rejected a seminal idea. Likewise, as Professor Ball's letter (page 640) shows, experimental help does not necessarily come from a grant-giving body.

No doubt all of this sounds like smug self-satisfaction; the real test for the openness of the system, it will be said, is bound to be in the case histories rather than in assertions of fairness. The problem with case histories, however, is that conclusions have to be drawn from limited evidence and that there is often considerable difficulty in understanding the spirit of the time. Wegener's advocacy of continental drift in the early years of this century is often quoted as an example of an immensely important idea on which the establishment turned its back, thereby retarding the earth sciences by fifty years. But Wegener's ideas were well known and widely discussed; continental drift was the subject of at least one conference in the 1920s. Causes of drift were discussed extensively in the literature. What was missing was the compelling evidence that Wegener could not provide and that only an expenditure of large sums of money on marine research in the 1960s could. That example should warn us that certain fields can fail to flourish, even when confronted with an apparently blinding insight.

It should also warn that the case history is not an easy way of demonstrating inbuilt bias amongst scientists unless it is possible fully to appreciate the environment of facts, observations and speculations within which they lived at that time.

Science is ultimately about ideas moving around inside people. It does not reside in textbooks or in large pieces of equipment. Although it is possible for individuals to deny to other individuals the access to hardware or the literature through one particular channel, it is possible for no-one to control all channels, and it is certainly impossible to suppress ideas and people. This may be less true in other societies or in other professions, but surely the Western scientific community has had a relatively good record, and it is time that we stood up and said so. □

All the food that's fit to eat

During the latter half of the nineteenth century the public outcry about the adulteration of food in Britain led to the passing in 1875 of the first effective Sale of Food and Drugs Act. This Act, which is the basis of our present law, contained for the first time the requirement that all food sold must be of the nature, substance or quality demanded by the purchaser. It also required local authorities to appoint public analysts to check for purity samples of food, drink and drugs procured by local authority inspectors. To celebrate the centenary of the Act a symposium was held in London this week.

DURING this year's Annual Meeting of the British Association, Professor P. J. Newbould, of the University of Bradford, read a paper on the basic purpose to which the endeavours of modern science-based societies were directed. During mediaeval times, he pointed out, while nations struggled, as we do today, to be prosperous, the main aim of their citizens was salvation. In our own day it is economic growth and technological advance.

The symposium organised by the Ministry of Agriculture, Fisheries and Food to celebrate the centenary of the passing of The Sale of Food and Drugs Act 1875 was hardly intended to question that the continuous accretion of legislation and the elaboration of food standards and regulations, one following the other as analytical refinements and the minutiae of nutritional understanding advanced, is anything but good, nor that further control and standardisation in the future will be better. Indeed, the title of the symposium was "Food quality and safety—

a century of progress". Yet it is to be hoped that the sheer weight and size of the programme left time for someone to consider whether Harry Lauder's advice in the old song, to "keep right on to the end of the road" is always applicable. Perhaps, if we look around from where Professor Newbould is standing we may find that we are already approaching the end of one road and could usefully consider going in another direction.

In 1875, adulteration of food was rampant. Those were the days when "little drops of water, little grains of sand (made) the milkman merry, and the grocer grand". Something needed to be done to stop the watering of milk, the addition of alum to flour and even so flagrant a malpractice as the use of "sugar of lead", as lead acetate was called, to sweeten beer. Progress in analytical chemistry made it possible to police the 1875 Act. It is worth noting that the Society of Public Analysts, now the Society for Analytical Chemistry, was also established

in 1875 with Theophilus Redwood as its first president. The main purport of the Act was to decree that food on sale should be of "the nature, substance and quality" demanded. Provided his product came up to this straightforward standard, the merchant was, like other citizens of the realm, a free man innocently selling anything he pleased until he was proved guilty of marketing a product not of the "nature, substance and quality" his customer could reasonably expect. The march of time, the progress of science and the development of food technology in all its modern ramifications and, most important of all, a change in the philosophical outlook of the community, have led today to a radical difference in the approach of those who guide our society to what constitutes good wholesome food and the means by which these qualities can best be maintained. To start with, the analyst's ability to detect smaller and smaller traces of contaminants has enormously increased. Figures in terms of p.p.b. (parts per 10⁹) are as commonplace nowadays as p.p.m. once were and for some compounds analysts can measure as little as 1 part in 10¹². Then again, the much simpler problem of determining whether a particular consumer had or had not suffered from poisoning by lead acetate immediately after having drunk adulterated beer is now replaced by the exceedingly difficult one of assessing whether, because a proportion of a colony of rats to which Butter Yellow had been administered developed cancer of the bladder, people consuming foods coloured with Butter Yellow would within a period of years extending up to 70 (it has only recently been decided that if the postulated harm is forecast as likely to occur later than this it can be ignored—after all, it does not much matter if you are poisoned after you are dead) be likely to suffer also. Nor could it be assumed that people who wished to buy a wrapped white sliced loaf, or mayonnaise from which an oily layer would not separate, or a jar of "coffee whitener", or a carton of soft margarine, or a can of luncheon meat knew any longer what "nature, substance and quality" it was that they were demanding—or so those responsible for the public welfare led the public to believe.

During the hundred years since 1875, the whole community comprising the ordinary citizen, the scientist, the diligent guardian of the public good and the food manufacturer have all been carried together along the stream of advancing technology. No longer do any of these consider that an ordinary person can be left to himself to recognise a sausage or a pot of jam. Step by step the law has taken it upon itself

to set up quantitative standards of composition, to lay down detailed specifications for what may appear on the label or in an advertisement. That is why it is forbidden any longer to sell a "digestive" biscuit, since the digestibility of all biscuits may be assumed, while Bristol Cream, deficient as it is in butter-fat content, retained its label by special dispensation. Only approved colours, preservatives, flavours and other substances added to improve the texture or retain the moisture—all so properly described as "additives"—can today be added. And behind all this stands the scientist who alone possesses the skill to determine whether the law has been obeyed and the rules kept.

Refinements of the present rules are coming as we watch. Already shopkeepers are being required on pain of prosecution to sell some foods before a predetermined date although so far it is not actionable to be caught eating stale bread. And the Food Standards Committee, recognising that beans are different from meat, are proposing that, should a manufacturer fabricate beans into the semblance and texture of meat, he should mix with them a due proportion of the amino acid methionine.

Clearly, it is important to insure that food is wholesome, uncontaminated by toxic substances and not misleadingly labelled. The question to be asked now, after a hundred years spent applying more and more scientific ingenuity, is whether the means have been justified by the ends that have been attained.

Have increasing health and happiness followed each addition of sophisticated control and regulation? Do labels bearing lists of "additives" in small print contribute to the contentment of those who eat baked beans, fish paste and tubs of margarine? The unification of standards of food composition and of the analytical procedure needed to verify their maintenance, first within the country as a whole, next throughout the European Economic Community and finally, as soon as can be done, across the whole world, is already in hand. A council of wise men such as that set up by James I to prepare an English version of the Bible is well advanced in its work to prepare the *Codex Alimentarius*, the world gospel of food composition.

Although it is right and proper for all these great men, distinguished in science and prominent in government and administration, nationally, internationally and world-wide, to review the progress that has been made, the end of a century of effort to apply science to the control of food quality and safety is a good time to stop, just as Professor Newbould has done, not

merely to see how nearly the target—of perfect quality and absolute safety—has been approached but to consider whether there is perhaps a different target to be shot at. Do people fuss and worry about the safety and wholesomeness of their food in spite of the devoted efforts of the Food Standards Committee, the Food Additives and Contaminants Committee and the Labelling of Food Regulations or because of them? Is the health of the community safeguarded more effectively by forbidding the use of cyclamates on the basis of subtle circumstantial evidence based on animal experimentation on which scientific opinions is, to say the least, divided or, let us say, by making cyclamates compulsory in order to minimise the consumption of sugar which is known to be harmful? There are other questions, likewise never asked, of which the biggest is: since, of all the contributing factors, lack of money is the most potent cause of poor diet, should we not measure the cost of the vitamin enrichment of bread and margarine, of analysis for the presence of required ingredients and the absence of proscribed ones, of the listing of components on labels, of the wrapping and packing of this and the discarding and disposal of that, to try to strike a balance between the benefits all these measures bring and the price that has to be paid for them.

These, however, are technical questions and, whatever shortcomings there still may be and whatever questions still remain unanswered, the distinguished people who set up the standards, do the analyses, measure the risks and add the vitamins are above all competent in their fields. The philosophy behind their century of forward march is, however, that of science and, as it sometimes seems, of a science that is assumed to be capable of ensuring that absolute safety and perfect purity—standards to which in the end all the world's food must conform. In the century ahead there is room for a new idea.

Obviously, our food must be fit to eat and we need to apply scientific understanding to keep it so. But, since there is no such thing as absolute safety, any more than there will ever be complete knowledge, there is room in the next century for those who invent the food laws to allow some of the people some of the time to eat at their own risk. Perhaps if the scientific advisers and governors let it thus be known that British scientists know that they do not know everything nor ever will and that they are not able to avert every "Act of God", the ordinary citizen would be less inclined to blame the government for every misfortune.

Magnus Pyke

One step from chemical automatons

by Akiyoshi Wada

By anyone's standards, the revelation of the molecular mechanism of life must be considered one of the highlights of the history of natural science. To make this revelation more meaningful and beneficial to mankind, those engaged in research on biological molecules must begin to think of possible practical applications of the molecular mechanism of life. For this purpose, a committee was formed in Japan about a year ago to examine and explore industrial applications of biological molecules with special emphasis on enzymes and other functional biopolymers. This is one of the projects under the auspices of the Council of Science and Technology in Japan for the promotion of life science. The committee is still carrying out its work, but wishes to present an interim report on the general image of what these applications might be, in the hope that it will stimulate a response from those who are engaged in biopolymer research.

A LIVING body is a molecular machine whose parts are molecules; machines using molecules as functional parts are obviously far more compact than present man-made machines. We already know the functions of individual parts, which make up complicated yet ordered chemical circuits. We also know how higher order structures are constructed and regulated, how energy is converted from one form to another, and how information is transmitted in these chemical circuits. The knowledge of these functions and mechanisms serves as the basis for the next stage of our project: the development of a chemical automaton with highly developed self-contained chemical circuits.

Rather like an electronic computer, this automaton would convert input into output; in the automaton's case, however, input and output would be molecules. An electronic computer is made up of hardware and software; a chemical automaton needs an additional component, a chemical reaction

system which might be called 'wetware'. The functional molecular units of a chemical automaton serve for:

- Reaction.
- Regulation.
- Information storage.
- Material transfer.
- Separation of materials.
- Transport of energy.
- Conversion of energy.
- Detection of parameters at each of the reaction stages.

The ultimate automaton is likely to be what might be called a 'synthetic living body' which consists mainly of wetware and software. But, for now we should concentrate on developing automatons which also include hardware such as measuring devices, computers and energy sources. For this purpose we must first develop the following topics:

- Stable and specific catalysis.
- Specific selective membranes.
- Reaction control systems including measuring devices.
- Chemical circuit theories.
- Energy transducers.

Topics in basic research which need to be studied and therefore to be supported for the development of the above items are:

- Biopolymers, in particular the structure and functions of enzymes.

- Molecular mechanisms of specific reactivity and its regulation.
- Organic reactions in aqueous and neutral conditions (without strong acids or bases).
- Synthesis of polymers of determined sequence.
- Stabilisation and immobilisation of natural enzymes for easy use.
- Specific permeable membranes.
- Mechanism of energy conversion in biological systems.
- Stability of chemical reactions in relation to spatial and temporal chemical oscillations.
- Development of highly sophisticated measurement techniques in physics and chemistry needed for the aforementioned research topics. (For example, we can cite the most up-to-date electronic and mechanical devices and computers.)

Many obstacles lie in the way of the realisation of chemical automatons. They may seem insurmountable, but in comparison with dreaming of flying 100 years ago, or speculating on high speed computers 50 years ago, chemical automatons are only a step away. In any event, nature provides chemical automatons as living bodies, and the principle behind their working mechanism is fairly well understood. Thus, the obstacles are indeed surmountable,

and efforts made in overcoming these obstacles are well worth exerting, when we think of the beneficial effects of chemical automatons on society.

Some of the direct effects would come from a new form of chemical industry, operating at normal temperature and pressure in the state of aqueous solution, requiring minimal energy and producing no harmful by-products. Other benefits would be flow production of complex chemicals which does not disturb the environment, and the possibility of the full use of substances abundantly available in nature, such as air, water and carbon dioxide.

Indirectly, chemical automatons would affect both basic and applied sciences covering a wide range of fields such as biophysics, molecular biology, biochemistry, polymer chemistry, the textile industry and the pharmaceutical industry.

In the advanced nations, including Japan, the potential for the development of chemical automatons is great. Barriers do, however, exist for such people to switch their specialities to life science. The automaton project straddles over many academic disciplines, and it is hoped that it could serve to trigger meaningful interdisciplinary research centring on the molecular life sciences. □

international news

Eight share Nobel Prizes

DURING the past week, Nobel Prizes for medicine, chemistry and physics, at £69,000 tax-free a time, have been shared by eight European and US scientists. The prize for medicine was shared by Renato Dulbecco, a 61-year-old Italian-born American now working at the Imperial Cancer Research Fund, London, and two of his former pupils—David Baltimore, aged 37, of the Massachusetts Institute of Technology, and Howard Temin (40), of the University of Wisconsin.

Baltimore was Dulbecco's student at the Salk Institute for Biological Studies, and Temin studied under him at the California Institute of Technology. They receive their prize for their work on the circumstances and effects which cause cancer. Dr Dulbecco's work has been on the mechanics by which animal viruses insert their own genetic material (DNA) into that of

animal cells. This can enable them to convert the cell into a virus factory, but it can also transform the cell into a cancerous state.

Dr Temin and Dr Baltimore share the credit for an outstanding discovery about RNA tumour viruses. RNA usually acts as the messenger molecule by which the genetic instructions of body cells are translated into proteins. Dr Temin and Dr Baltimore were convinced that RNA tumour viruses must be able to reproduce themselves in a DNA form to enter the cell's genetic machinery. Ten years after Dr Temin first predicted it, both men almost simultaneously found the enzyme that enables them to do it. The enzyme enables the virus to make DNA from RNA.

The discovery stood conventional biology on its head because it reversed the genetic process by which DNA makes RNA and RNA then makes protein.

Many RNA viruses are involved in animal cancers and it is believed that some human cancers may be caused in the same way. Work with these viruses

has also shed considerable light on the basis of the genetic workings of cells.

The chemistry prize was shared by John Cornforth (58), now at the University of Sussex, and Vladimir Prelog (69), a Yugoslav-born Swiss citizen who teaches organic chemistry at the Federal Institute of Technology in Zurich. The Royal Swedish Academy of Sciences said that Cornforth, who has been deaf since childhood, had made "an outstanding intellectual achievement" in his work on the stereochemistry of enzyme-catalysed reactions.

Professor Cornforth has used enzymes, which are natural biological catalysts for speeding chemical reactions, to look at the synthesis of biological molecules. In particular, he has shown the steps by which cholesterol is made.

Dr Prelog has contributed to an understanding of how natural molecules are often produced in an asymmetrical fashion. Many molecules can exist either in a "right-handed" or in a "left-handed" form. Artificial manufacture of such molecules generally produces equal amounts of each. But in nature, only one is produced.

An American and two Danish nuclear scientists shared the physics prize for research into the structure of atoms. They are James Rainwater, of Columbia University, New York; Aage Bohr, of the Niels Bohr Institute, Copenhagen; and Ben Mottelson, of Nordita, Copenhagen.

Rainwater, Bohr and Mottelson won their prize for the invention of the 'collective' model of the nucleus. This is a synthesis of two earlier models: the liquid-drop model (a rather coarse, very 'collective' model in which the nucleus is pictured as a charged drop which deforms as a whole; it was very successful in explaining the masses of nuclei and fission) and the shell model (in which nucleons are pictured as existing in individual orbits and forming closed shells; this leads to the idea of 'magic numbers'—particular numbers of nucleons conferring exceptional stability on the nucleus).

The latter model was much more detailed in its treatment of the nucleus, and one could derive much more information about excited states from it. Experimental deficiencies were observed, however; many nuclei exhibited much greater quadrupole resonances than could be explained on the shell model, and also some nuclei showed an excited level structure reminiscent of rotational bands. The collective model pictures the outer nucleons, in individual orbits, interacting with the closed inner shells and deforming them—this gives the 'collective' effect, and achieves the synthesis of the two models. □

Education issues in Japan

ONE of the most commonly quoted statistics about Japanese higher education is that graduates comprise only about 3% of total student numbers (compared, say, with the UK where graduates comprise 20% of all students). What is less often mentioned is that even this 3% meant 46,000 graduate students in 1973—more than in the UK. Even so, the concept of the graduate course as an integral part of the structure of a university is less common in Japan. As the table shows, half of all universities do not have such courses.

Since the Second World War the number of universities in Japan has increased enormously. For national universities the government took the view that newly established institutions should not have graduate courses; rather, the courses in the former imperial universities should be enlarged in size and scope. Some additional financial support was forthcoming for research and education, but in general staff numbers and facilities were not allowed to increase.

This selective funding, however, was seen to widen the gap between research activities in universities with and without graduate schools, so great, almost fanatical, pressures developed in the early 1960s to develop graduate courses. Originally such courses were intended primarily to educate new research scientists, but industry increasingly demanded people with master's degrees, many of which courses are now much more closely related to production processes than to research.

The market for people with doctorates is limited to universities and the research institutes of government and private industry. But enrolment in higher education seems to be reaching saturation, so universities are no longer taking on many new staff; the same is true of most other institutions, with exceptions only in the environmental and social sciences. The problem of the so-called 'over-doctors' is serious, and many have proposed an increase in the number of postdoctoral fellowships as a way of preserving a reservoir of highly qualified manpower for future demands.

The Japanese concept of the chair (*koza*) undoubtedly had its origins in the European professorial chair, although there are many differences.

It is the structural unit of the faculty, responsible for education and research in a specific subject area, and is composed basically of one professor, one assistant professor and two assistants. It is provided with its own running expenses and facilities. Although often criticised as an indestructible castle of conservatism and hierarchy, it functioned reasonably well in the pre-war imperial university, and has also been fitted into the present frame-work of graduate education. Partly because of the rapid expansion of the size of enrolment, and partly because of the enormous development of the sciences, the idea emerged that it would be more desirable to lift the restriction that the structural unit for education should be identical with that for research. It was hoped that this would make teaching as well as research more flexible and dynamic. After lengthy discussions, the laws governing the structure of the universities, both national and private, have been modified to allow the possibility of avoiding the traditional structure of the faculty based on the *koza* system, and to admit a more flexible one. Any new venture has to be discussed with the Ministry of Education, of course.

One of the issues from a recent report from the University Council (*Daigaku-setchi Shingikai*) in the Ministry of Education is the possibility of independent graduate institutions outside the universities. Although apparently a reasonable proposal, and even though such an institution may be highly qualified in research, there still needs to be an appropriate mechanism to link research with the educational background characteristic of a university. The lack of a mechanism for encouraging interaction between research and education could be harmful. The report also mentioned that it would be worth considering associated graduate institutions administered through the cooperation of several universities. Serious efforts are being made in certain groups of universities (including cooperation between national and private universities) to encourage the exchange of teaching staffs or of student credits. These changes will be particularly useful in developing interdisciplinary courses such as information science or environmental science.

Anti-nuclear critic faces dismissal

by Allan Piper

A LEADING West German nuclear scientist is faced with dismissal from his chair at the University of Bremen, apparently because of his support for the anti-nuclear energy lobby. Dr Jens Scheer, Professor of Nuclear Physics at Bremen and a state parliamentary candidate for the German communist party (KPD), has claimed that the action against him arises out of his active criticism of the West German nuclear programme, and that it is not a consequence of his political affiliations, as is officially claimed.

Professor Scheer was suspended on September 23 following his alleged involvement in a disturbance on the university campus during which the officials of a civil court were attacked by egg throwers. Though he denies the charge he will now face a special disciplinary tribunal. The University authorities have stated that they are seeking his dismissal, the official reason given being that Professor Scheer, as a member of the KPD, has contravened "the code of honour which every [civil servant] must, through his whole behaviour profess and seek to maintain". Although as head of a university department Professor Scheer holds what is effectively a life appointment under existing German law, his dismissal on those grounds would be perfectly in order. A growing body of support for him maintains, however, that a little used legal clause has been invoked to mask the real reason for dismissal.

Professor Scheer's supporters, including a large number of eminent European academics and political organisations, believe that in seeking to remove him from his position at the university, the authorities hope to overcome a potentially powerful source of opposition to the West German nuclear energy programme. As yet Germany has no nationally coordinated anti-nuclear lobby but in the past Professor Scheer has often provided expert support for small, local protest organisations. Further, since his arrival at Bremen in 1971 Professor Scheer has established his department as a centre for the study of the interactions between science, technology and society, and in May this year the department published a book examining the strategy and consequences of nuclear development.

● Yesterday it was learnt that Professor Scheer's suspension has been overruled by a court of law, allowing him to resume his normal duties at the university, but dismissal proceedings will still go ahead. □

AN international group of scientists involved in bacteriophage work is unhappy about the way in which the Recombinant DNA Molecule Program Advisory Committee is handling the problems of plasmid engineering, and a meeting of the committee planned for this month has been put off until December because of the concern which has been expressed about its last meeting at Woods Hole.

The group, which consists of 48 scientists who attended the recent Cold Spring Harbor bacteriophage meeting, has sent a petition to the National Institutes of Health (NIH), complaining that the Woods Hole guidelines on recombinant DNA represent a watering down of the recommendations made at the Asilomar conference earlier this year. The Asilomar conference, convened by Professor Paul Berg, was the first gathering of workers in the field to discuss the potential dangers of plasmid engineering, and a subsequent meeting of UK workers at Oxford broadly confirmed the working rules suggested at Asilomar.

In a letter to Dr Dewitt Stetten, Deputy Director for Science, Office of the Director, NIH, the Cold Spring Harbor people complain that a draft of the Woods Hole meeting called "Current Guidelines for Research on

Recombinant DNA Molecules" appears "to lower substantially the safety standards set and accepted by the scientific community as represented at the meeting at Asilomar in February, 1975".

DNA committee has its critics

The letter "strongly requests" that the advisory committee considers at its postponed meeting the feelings of the group in three areas.

- They urge that the most hazardous experiments be curtailed until some experimental determination of the risks inherent in such procedures is made. They say, for instance, that the extent of containment possible with different vectors remains to be shown.

- They are concerned that any mammalian DNA (let alone animal viral DNA) can, by the present draft, be cloned under less than P3 containment, and they say that they are not persuaded that an untested vector designed for safety reasons is by itself an adequate safeguard for such experiments in an open laboratory. They add that "strong consideration should be given to limiting shotgun experiments of mammalian DNA to P4 contain-

ment until proven safety vectors are available".

- They feel that the composition of the committee should be broadened to include more representation from the areas of animal virology, plant pathology and genetics, and epidemiology; and also that the advisory committee should have much stronger representation from scientists not directly involved in cloning experiments. And taking a line which the committee will surely find hard to swallow, they think it advisable "to consider representation of the public at large".

One of the organisers of the petition, Richard N. Goldstein, of the Harvard Medical School, says the letter "reflects a deep concern" with the results of the Woods Hole meeting, and he believes it is "exceedingly important that the general scientific community be made aware of these developments".

- This week Dr Goldstein reported that the Woods Hole guidelines had been scrapped. According to Goldstein, Dr Betty Kutter, "a vocal critic of these guidelines and a member of the Recombinant DNA Molecule Committee, has been charged with the re-writing of these guidelines as a result of the pressure put on the committee by many dissatisfied scientists".

EVER since the days when medicine was largely the province of hucksters and snake oil merchants, people have been touting cures for cancer. Nowadays, such cures may be mentioned briefly in a racy tabloid newspaper, but they are usually ignored by self-respecting scientists, attract mercifully little following, and are quickly forgotten. But not so with one purported anti-cancer remedy called Laetrile.

Although declared contraband by the federal government, outlawed by several state governments and found to be utterly worthless in a number of tests carried out at several prestigious cancer research institutes, Laetrile is now being consumed by an estimated 20,000 people in the United States. It is available on the black market, or through clinics in Mexico and West Germany, to which desperate American cancer sufferers are flocking in droves. It owes its popularity in the United States to a vocal, and at times heated, campaign by a number of groups on the West Coast who are fighting to get legal restrictions on Laetrile lifted.

The bitter battle over Laetrile would have all the ingredients of a good thriller, if the subject matter were not so tragic. Research reports have been stolen and given wide publicity, an international smuggling ring has been broken up by federal agents, cancer

Trials for Laetrile

by Colin Norman, Washington

researchers have been accused of deliberately suppressing information, numerous court fights have occurred, and right-wing political groups have been accusing the government of invading personal freedom. The matter has certainly caused a headache for the Food and Drug Administration and the National Cancer Institute, and a good deal of embarrassment for the Memorial Sloan-Kettering Cancer Center in New York.

Laetrile was apparently first used for cancer treatment in the 1920s by a California doctor called Ernest T. Krebs, Sr, but it was too toxic to be much use. A purified form was developed in 1951 by Krebs' son, E. T. Krebs, Jr, a biochemist, who claimed that the substance was safe for injection. More recently, Laetrile has been produced in a form which can be taken orally, and its use has skyrocketed.

There have been numerous anecdotal reports of cancer sufferers who have gone into remission after taking Laetrile, or who have at least experienced a cessation of pain and have died in relative peace. But there have been no formal, clinical trials to test the efficacy of the substance, and until recently

there have been few animal trials to test Laetrile's purported anti-cancer activity. Results of two extensive animal trials will, however, be published later this month. They are unambiguously and crushingly negative.

Proponents of Laetrile have even suggested an elaborate mechanism to explain its alleged action. The substance, they suggest, is broken down inside cancer cells by the enzyme β -glucosidase, to release benzaldehyde and hydrogen cyanide in sufficient quantities to kill the malignant cells. Normal cells, they suggest, are protected because they contain the enzyme rhodanese which, in the presence of thiosulphate, converts hydrogen cyanide to the less toxic thiocyanate. It is a neat mechanism which every cancer chemotherapist looks for—something which is entirely specific to cancer cells but non-toxic to normal cells. The trouble is, though, that there is not a shred of evidence so far to support it.

The campaign in support of Laetrile certainly has considerable popular appeal. A film developed for the pro-Laetrile forces, for example, begins with the following statement: "This year, 250,000 Americans will die from cancer . . . this great human tragedy can be stopped now entirely on the basis of existing scientific knowledge". It goes on to note that "the history of science is the history of struggle

against entrenched error", and that some of the greatest scientists were ridiculed in their own time. It states that "with billions of dollars spent each year on research, with other billions taken in from the cancer-related sale of drugs, and with vote-hungry politicians promising ever increasing government programs, we find that, today, there are more people making a living from cancer than are dying from it", and argues that scientists therefore don't really want to find a cure for cancer because "if the riddle were solved by a simple vitamin [Laetrile], this giant commercial and political industry could be wiped out overnight".

In 1972 and 1973, the campaign took a new tack. Petitions, said to be signed by 43,000 people, were sent to former President Nixon demanding that clinical trials be run on Laetrile to test its anti-cancer properties. The petitions were responsible for launching four animal studies: two were carried out under contract to the National Cancer Institute (NCI), and two others were performed at the Memorial Sloan-Kettering Cancer Center and the Catholic Medical Center in Queens, New York.

Results of the two NCI studies will be reported later this month in the September/October issue of *Cancer Chemotherapy Reports*, a journal published by the NCI. Conducted by Isidore Wodinsky and Joseph Swiniarski at Arthur D. Little Inc. (ADL) in Cambridge, Massachusetts, and by W. R. Laster, Jr, and F. M. Schabel, Jr, at the Southern Research Institute (SRI) in Birmingham, Alabama, the studies involved large doses of Laetrile administered to mice bearing transplanted tumours. A standard method of screening for anti-cancer drugs, it consists of transplanting pieces of tumour from one mouse into other, genetically identical, mice and observing the effects of drugs on tumour growth. The ADL studies involved four different types of cancer, and the SRI tests three.

According to Wodinsky and Swiniarski, Laetrile did not prolong the life span of mice bearing any of the transplanted tumours, even at doses close to the level at which the substance was found to be toxic. They therefore conclude that "no anti-tumour activity was found in any of the four systems tested". Similar results were reported on the basis of the SRI tests. Laster and Schabel conclude that Laetrile "did not demonstrate significant anti-tumour activity against any of these three tumour systems".

Such negative results would normally be sufficient to close the book on a possible anti-cancer agent, but not Laetrile. The studies at the Sloan-Kettering have, inadvertently, provided

some ammunition for the pro-Laetrile forces.

According to Dr C. Chester Stock, a vice-president of Sloan-Kettering, and director of the institute's Walker Laboratories, his institute took a brief look at Laetrile in the early 1950s, but found no effect when it was tested against one implanted tumour system. The work was then dropped because "other agents were showing promising activity", he said. But when the petitions started flooding into the White House and letters began arriving at the Sloan-Kettering, demanding that Laetrile be tested, it was decided that the institute should take a second look at the substance. Particularly pertinent to that decision was the fact that the chairman of the President's Cancer Panel, Benno C. Schmidt, is also a board member of the Sloan-Kettering Institute (SKI). According to Stock, tests were run on "a battery of transplanted tumours" at high doses, in 1972, but he said "we didn't see any benefit whatsoever"—Laetrile again proved to be ineffective as an anti-tumour agent.

Although the use of transplanted tumours is a standard procedure for testing anti-cancer drugs, it has recently come under considerable criticism on the grounds that transplanted tumours may not behave like spontaneously occurring ones. The decision was therefore made at the SKI to test Laetrile on a strain of mice (developed by Dr Daniel Martin at the Catholic Medical Centre) which has a very high incidence of spontaneous mammary tumours. The tests were begun in 1972 by one of the SKI's most venerable researchers, Kanematsu Sugiura.

Sugiura's initial studies seemed to show a surprising effect. Although Laetrile apparently had only a small and variable effect on the primary tumours, it seemed to have a marked effect on the appearance of lung metastases. According to tests run between September 1972 and June 1973, Sugiura found that whereas 78% of the mice in control groups had lung metastases present, only 17% of those treated with Laetrile developed metastases. Sugiura wrote up the results of his experiments in a report which he circulated to his colleagues.

In the autumn of 1973, somebody at the SKI sent a copy of Sugiura's report to Laetrile proponents on the West Coast, and it subsequently got banner headline treatment. Supporters of Laetrile began to claim that the prestigious Sloan-Kettering Institute had proven the effectiveness of Laetrile, and that the institute was suppressing the results.

Since that time, Sugiura has continued to study the effect of Laetrile

on spontaneous mammary tumours in the mice bred by Martin, and parallel tests have been run by two other researchers at the SKI and by Martin himself. Sugiura has continued to find that Laetrile seems to inhibit the formation of lung metastases, but the other three investigators have all come up with negative results. Reports of Sugiura's recent research have been circulated within the SKI, and a month or two ago they were again leaked to Laetrile proponents on the West Coast, who distributed them widely to the general press.

In view of the wide publicity which the studies have received, and the charges that the SKI has been suppressing results favourable to Laetrile, Dr Stock recently discussed the issue.

Stock said that "because of the emotion surrounding this issue, we felt that we should be cautious". It was agreed that Sugiura and Martin should cooperate in a test on Laetrile in mid-1974. The experiment proceeded in exactly the same manner as Sugiura's earlier studies, except that lungs from the mice were subjected both to microscopic examination and to bioassay—the lungs were transplanted into a fresh animal to see whether tumours grew. Bioassay provides an objective assessment of whether or not lung metastases were present. The results proved negative—there was no difference between mice treated with Laetrile and the controls. Similarly, Stock said that the two other SKI studies proved to be negative.

Thomas emphasised that the SKI has certainly made no attempt to suppress results favourable to Laetrile, and he said that "I think it is safe to say that if it had been any other agent under study, we would have lost interest in it" when Sugiura's early results seemed to indicate that it had little or no effect on primary tumours.

The fact remains, however, that in spite of a large, and growing, body of information which indicates that Laetrile has no anti-tumour effect in animal systems, the substance is continuing to grow in popularity, and its proponents remain convinced of its efficacy. They are still demanding that human trials should take place.

Most cancer specialists are adamant that clinical trials are certainly not justified. Thomas, for example, said that "in the absence of positive data from animal experiments, use of Laetrile in human beings with cancer remains extremely difficult to justify, particularly in patients with cancers that are treatable by surgery, radiotherapy or chemotherapy". The Food and Drug Administration (FDA), which would have to licence any clinical trials, agrees. An FDA official pointed out that it would be difficult to

It is not, I hope, a serious contravention of the Official Secrets Act to reveal that, in Committee Room 11 in the Houses of Parliament, the wall above the rostrum is adorned with an enormous oil painting which depicts "The Speakers Procession in 1884". The Parliamentary and Scientific Committee sometimes meets in this room, and when the proceedings are less than enthralling I find myself studying the picture. My interest is not so much in attempting to identify the impressive figures (the print on the key diagram is too small to be read at a distance) as in wondering at the appalling mess of litter and waste paper through which the procession is wading. It is almost like the platform of a London underground railway station in 1975. I am glad to say that the corridors of power are, in this respect, more hygienic today, if other places are becoming filthier.

Litter and refuse are undoubtedly providing some of our most difficult pollution problems today. Both New York and London seem to be permanently subject to piles of stinking refuse, even when there is no industrial dispute between the local authorities and the refuse collectors. Earlier this year the strike of dustcart operators in Glasgow faced the city with a serious public health problem, so that the army had to be called in to clear away the more noisome dumps. The problem is made worse by the way in which the bulk of the litter is swelled by masses of unnecessary packing material, but its danger is also a function of affluence, for it is the waste food, much of it initially quite fit for consumption, that makes refuse a public health problem, attracting rats and increasing the risk of transmission of disease.

What may not be generally realised is that it is the successful control of air pollution which exacerbates the problem. Earlier this century the volume of refuse was much smaller, partly because much was burned on domestic grates and kitchen ranges.

It is true that some of the more

affluent do have refuse disposal units, to pulverise food and some other wastes, which are then discharged into the sewers. This may allow their hygienic disposal, though there have been reports from America of a consequent overload of sewage works and even more serious pollution of rivers when the material is discharged, untreated, into them. We are often better at moving pollution from one place to another than in curing or controlling it.

The Chief Scientist to the Ministry

Waste line

KENNETH MELLANBY

of Agriculture, Fisheries and Food, has recently stated that, of the food bought in Britain, as much as a quarter may be wasted. This does not include the substantial amount that is eaten, over and above their actual requirements, by most of our population, contributing to the obesity which is the most serious symptom of malnutrition in most Western countries today. It seems likely that, if we eliminated waste and gluttony, we could reduce our balance of payments deficit by nearly £1,000 million, without any marked change in our feeding habits.

Although there is a growing interest in recycling all types of waste material, little food is re-used in this way. In the past, much pig swill came from hotels, schools and even from private houses. Since swine vesicular disease has

become a serious problem, such collections of swill have greatly decreased, as regulations to ensure that the food is properly treated and sterilised, though wise and necessary, are too stringent for the majority of small operators. It is calculated that the dustbins of Britain contain at least 3 million tons of "putrescible material" (the trade jargon for waste food) a year, much with a high protein content, and that if this were properly treated it could feed more than 1 million pigs—as well as reducing the health risks arising from uncollected refuse.

If waste food is to be used to feed animals, it has to be separated and treated. There are less difficulties in recycling refuse as a soil fertiliser or conditioner. Considerable amounts of sewage sludge are used in this way, and several cities have installed elaborate and expensive plant to produce municipal compost. Wastes brought in by the dustcarts are sorted and separated (tins and iron scrap is removed magnetically, baled and sold) and the remainder, with added sewage sludge, goes through a digestive process. The end product is a brown powder which is quite pleasant to handle. It contains a significant amount of nutritive salts, and is an excellent conditioner for intractable clay soils. Although available at a low cost, most farmers have been reluctant to use municipal compost, because it usually contains substantial amounts of heavy metals, the lead level commonly exceeding 200 p.p.m. There is evidence that, in the presence of a high level of organic matter, this lead is hardly taken up by most plants, but it does remain in the soil and might give rise to problems at a later date if the organic level fell substantially.

Waste disposal and re-use is thus seen to be a very complicated problem. Clearly the best solution is to produce less, and to see that what cannot be avoided does not give rise to further problems. But it is at least encouraging that our present Members of Parliament are better house trained than their Victorian predecessors.

design an acceptable clinical trial without depriving patients of other, accepted methods of treatment. In other words, if Laetrile were put on clinical trial, it could only be justified ethically if it were simply added to other forms of treatment, and that wouldn't make for a very rigorous test.

There is, however, another extremely important aspect to the Laetrile debate. Laetrile, in its purified form, is relatively non-toxic. It can be fed to animals in large doses before any adverse effects are noted; according to Thomas, at least one of the "solid

pieces of data" to come out of the SKI studies is confirmation of that fact. Laetrile proponents therefore argue that FDA should not regulate the substance as a drug, but as a food or even a vitamin.

Would it do any harm if the FDA were to allow Laetrile to be marketed like any other so-called health food? Even the *New York Times* has suggested, in an editorial published in August, that since Laetrile is usually taken by cancer patients who are beyond help from conventional therapies, they should not be denied even a

possible placebo effect from the substance. But a letter from Dr Sherwin Gardner, Deputy Commissioner of the FDA, took exception to that suggestion. Pointing out that the FDA has a duty to protect the public against ineffective drugs, Gardner said he believes that "the idea of fraudulent promotion and sale of bogus cures to the desperately ill and dying is appalling". It is also argued that, if Laetrile is made more widely available, it will be taken by cancer patients in preference to other therapies which have at least proved effective in the past. □

correspondence

Laboratory charges

SIR,—I am much in sympathy with Kenneth Mellanby (October 2) and especially his final paragraph on inexpensive biological research. Having simple research needs—eyes, a waterproof and time for fieldwork and contemplation—I have been conscious throughout my career as a littoral ecologist, of the patronising designation 'only a naturalist' from those who think that little of value can be achieved without, for example, an autoanalyser, an atomic absorption spectrophotometer or an electron microscope. Tempted though I have been at times to try to impress visitors with a benchful of borrowed equipment and some coloured liquids their attitude has nevertheless remained as water on a limpet's back, and the major events of recent years have finally reinforced my conviction that a field of biology that is important but relatively inexpensive, that appears simple but is very challenging, has been ignored in favour of the esoteric and the elaborate.

This event is the 'ecological crisis', and more particularly within my own discipline the dawning realisation that by generally eschewing organismal biology for several decades marine biologists are not now able to tell society with conviction the state of affairs in the sea or along the coast. Time after time one is asked if pollution is affecting local populations, if a scarcity of this or an abundance of that is natural or not. With embarrassment one admits to ignorance, except in obviously severe instances, and then, in response to mutterings about taxpayers' money and what biologists have been doing all these years, one loyally defends colleagues who did not find it worthwhile intellectually or in career terms to count organisms, or to study their biological interactions, their reproductive cycles, their behaviour or even how long they live—all of which would have better enabled us to assess the present field situation and respond to the public concern. But attitudes are changing; the doom-mongers have, after all, done biology a service.

To those who may wonder what to turn to if their capital investment should be rendered valueless by an inability to meet the unforeseen but swingeing maintenance contracts, may I offer a suggestion? Lend a hand on a field course and encourage accurate

observation and speculation about what organisms do, how they live in a complex natural situation. The range of as yet unanswerable questions about even the most common species that will surely arise from a class of enquiring minds will not only be humbling but will point to many rewarding research projects. In short, natural history appears in many up-dated guises but still presents unlimited and relevant challenges.

Yours faithfully,

J. R. LEWIS

This week's free offer

SIR,—In a recent BBC "Controversy" programme, Professor John Taylor expressed strongly his opinion that scientists were stifling science. One of his points of contention was that he had been unable to obtain a grant from the Science Research Council to support investigations into the supposed paranormal phenomena associated with Uri Geller and others, including some children. In discussion he said that he had not the facilities for a thoroughgoing scientifically controlled experiment and mentioned that these could include such expensive items as electron microscopes and audiovisual recording equipment.

The phenomenon most frequently mentioned is the deformation and fracture of metallic objects without the application of the relatively large stresses normally to be associated with such changes in the metal shape. If it were true and could be substantiated, this would be an entirely new metallurgical phenomenon.

The equipment required for its investigation, including all the items mentioned by Professor Taylor, is available in this department and could be used for a definitive experiment. I would therefore like to invite Professor Taylor to join with us in devising a controlled experiment which would test the authenticity of the claims made by those, and particularly Uri Geller, who say that they can bend metallic objects without the direct application of the stresses normally required.

I would suggest that to establish the experiment's authenticity, its control and observation by independent witnesses should be approved beforehand by yourself and/or a nominated panel

of scientists and conjurers. The experiment could be devised to be definitive and its cost would be very small in relation to the importance of the claims that have been made. Professor Taylor need have no recourse to financial resources as the conduct of the experiment would be within the normal research activities of a department such as this. I very much hope that Professor Taylor will be willing to take up this proposal.

Yours faithfully,

J. G. BALL

Imperial College, London, UK*

Cheating children

SIR,—Professor Taylor has cited a remark of Sir William Crookes on the relative susceptibility to deception of physicists and conjurers. It would materially help in weighing this statement if he would tell us whether it was uttered before or after Sir William had disgraced the scientific calling by becoming an accomplice of the fake medium Eliza Cook; if the latter, was it before or after the conjurer Maskelyne indicated the mechanism of deceit?

Yours faithfully,

M HAMMERTON

Out of town

SIR,—May a humble linguist point out that "commanded out" ("Publishing problems", September 4) is probably an attempted translation of the German *abkommandiert*, which is a military (and probably bureaucratic) term meaning "temporarily transferred" to another place ("detached" is the English term as opposed to a permanent "posting"). Central Europeans, particularly scientists and technologists, often use German as a lingua franca; and central Europeans tend to be rather 'disciplined' in their jargon as opposed to the trendy Anglo-American 'free-and-easy' style. It is all a matter of custom. Without prejudice to your correspondent's point, his friend may merely have meant to say "I was out of town for a couple of weeks, and couldn't reply earlier".

Yours faithfully,

A. LODGE

Swanley, Kent, UK

news and views

Recent developments in scrapie

from Richard H. Kimberlin

FOR over a decade scrapie has excited the interest of scientists in all parts of the world because of the unusual nature of the disease and its causal agent; few diseases have aroused so much discussion and speculation.

Originally scrapie was studied as an important disease of sheep which, after a very long incubation period, can be recognised by the characteristic signs of uncoordinated movement and "scraping" or rubbing of the skin. These signs are associated with damage to the brain and, under the light microscope, the brain lesions appear mainly as vacuolation. It is now recognised, however, that sheep scrapie is the best known member of a larger group of diseases that includes transmissible mink encephalopathy (TME) and the two diseases of man, kuru and Creutzfeldt-Jakob disease, all of which have a similar brain pathology. Some recent studies of scrapie and TME in golden hamsters have shown that these diseases are almost indistinguishable either histologically, biochemically or biologically when compared in a common experimental host (Kimberlin and Marsh; Marsh and Kimberlin, *J. infect. Dis.*, **131**, 97-103, 104-110; 1975). It now looks as though scrapie may be important in studies of an even wider group of diseases because some strains of the scrapie agent can produce cerebral amyloid deposits in mice which are broadly similar to the amyloid plaques seen in aged human beings and in some neurological disorders of man such as Alzheimer's disease and Down's syndrome (Bruce and Fraser, *Neuropathol. appl. Neurobiol.*, **1**, 189-202; 1975).

Most of our knowledge of scrapie has come from studies of the disease in mice. The length of incubation is influenced by many factors such as the amount of agent and the genotype of mouse and, depending on these variables, it can be as short as 100 days or may exceed the lifespan of the host (Dickinson *et al.*, *Nature*, **256**, 732-733; 1975). Particularly impressive is the remarkable predictability of incubation period under defined conditions of infection. In most cases the incubation time can be measured with a standard error of only 1 or 2% of the mean suggesting an almost clockwork-like precision in the development of disease. Multiplication of the agent occupies much of the incubation period. When peripheral routes of infection are used the agent multiplies initially in extra-

neural tissues such as the spleen. Only later does agent become detectable in brain and the amount of agent increases slowly until clinically recognisable disease develops.

There is little doubt that the long incubation time is due to the slow rate of agent multiplication in brain. It is known that the dynamics of agent multiplication are under the control of a gene called *src* and there is increasing evidence that the slowness of the process is due to a host restriction on the number of replication sites. The most convincing evidence of this comes from the demonstration that the previous injection of a strain of agent that is "slow" in a given mouse genotype can completely block a "fast" agent injected later (Dickinson *et al.*, *Nature*, **253**, 556, 1975). The interference phenomenon is most simply explained in terms of the "slow" agent occupying replication sites which would otherwise be available to the "fast" agent.

To appreciate the significance of these findings it should be emphasised that no humoral or cell-mediated response to scrapie infection is apparent during the incubation period, that is, there is no evidence that "competition" between agents has an immunological basis. Similarly, prolonged depression of T or B lymphocyte functions has no effect on incubation period and there is substantial evidence that interferon plays no significant role in scrapie pathogenesis.

Despite the limited role of conventional host defence mechanisms there are clear indications of some kind of scrapie inactivation system in mice. Moreover, the importance of spleen (and probably other extraneural tissues) in the early multiplication of agent indicates the importance of some components of the lymphoreticular system. The question is—which cells are involved in these scrapie-inactivation and scrapie-multiplication processes?

Even though there is no evidence of an inflammatory reaction in scrapie brain there is a suggestion that an in-

flammatory response may be important because it is now known that injection of mice with prednisone acetate or with arachis oil (both of which suppress inflammation) can prolong the incubation period (Outram *et al.*, *Lancet*, **i**, 198-200; 1975). It is particularly interesting that these drug treatments need only be given for a very short period around the time of scrapie infection by a peripheral route, suggesting that they influence some of the cellular events involved in determining the "speed" of the scrapie "clock". These early interactions between scrapie agents and host cells will clearly be of great importance in future studies of scrapie pathogenesis.

The physicochemical nature of scrapie agents is another fundamental question that needs to be answered. This has been an exceptionally difficult problem to study for several reasons—no one has consistently identified virus-like particles in scrapie preparations using the electron microscope, so we don't really know what kind of agent to look for and immunological and tissue culture methods are not available for measuring amounts of agent. This can only be done by infectivity assays which in mice are very time consuming because of the long incubation period. Also, no-one has succeeded in obtaining purified preparations of scrapie agent which would make characterisation so much easier. Many standard virological techniques are therefore inapplicable to scrapie research and somewhat indirect methods have been used, mainly based on studying the effects of various physical and chemical treatments on scrapie infectivity (Hunter, *Prog. med. Virol.*, **18**, 289-306; 1974). These studies have revealed a number of important clues.

In general, scrapie agents are very stable to many treatments which would be expected to inactivate most conventional viruses. This stability may be related to the intimate association of infectivity with cell membranes. The smallest membrane fragments with infectivity have a diameter less than 50 nm. Important studies by Haig, Alper and others of the effects of ultraviolet and ionising radiation suggest, however, that the scrapie-specific portion of infective membrane fragments (the portion that codes for different strains of scrapie) may be much smaller. Despite past controversy, there is no good reason why the scrapie-specific portion should not be nucleic acid, in which case the ionising radia-

tion data suggests that it may have a molecular weight of 150,000 daltons (about the same size as viroid RNA). Therefore the simplest working hypothesis suggests that the infectious scrapie agent is made up of a small specific nucleic acid intimately associated with membranes of the host cell. Implicit in this model is the concept that scrapie agents do not exist as discrete virions which can be easily separated from cell components.

Against this background it is interesting to read the paper by Cho and Greig on page 685 of this issue of *Nature* in which the isolation of 14 nm virus-like particles from mouse brain infected with scrapie agent is described. The authors have been very careful to state that "it is not known whether these particles are indeed the scrapie agent" which is an honest admission that so far there is no evidence of whether these particles have scrapie activity. This is an important point because experience in cancer research has taught us to be wary of accepting an aetio-

logical role for viruses isolated from diseased tissues. The central nervous system is a well known repository of persistent and latent viruses which may or may not be involved in disease. It is quite conceivable that the particles isolated by Cho and Greig represent a virus which is present in brain and may be activated by scrapie infection but which plays no role in the disease.

The crucial questions to answer are do these particles *per se* have high specific scrapie activity and can they be isolated from other tissues such as spleen and from other hosts infected with other strains of agent?

If the answer to both these questions is yes then the findings of Cho and Greig will considerably alter our thinking on the nature of scrapie agents but, more importantly, they will provide purified particles that will make physicochemical characterisation so much easier. If the answer is no, then the authors have apparently purified a virus-like particle which may still be of interest because of its small size. □

origin in the lateral growth zone. That is the conclusion Scholes has drawn from labelling DNA in the growing fish retina, where the label appears in synchronised waves in the red, or the blue, or the green cones but is never seen to spread laterally in the receptor layer, and so must presumably be travelling vertically.

Spatial frequency channels

Lamb's talk was followed by a scintillating review from Fergus Campbell (Cambridge University) on the psychophysical evidence for spatial frequency channels in human vision, which are not explicable at the receptor level. Horace Barlow, from the chair, raised the question of how to explain, at any level, how the Fourier analysis which Campbell has suggested as the basis for the frequency response can be combined with the retention of precise positional information. Campbell's response was to concede that the Fourier analysis must be done piecewise, so that much of the information in the frequency channels is positional and only some of it is broken down into spatial frequencies. As the physiological substrate for this dichotomy, however, he suggested that spatial frequencies might be coded in the large, fast-adapting Y fibres of the optic nerve and position in the slow X fibres. That remark elicited a fascinating case history from Geoffrey Arden, who has been using new television techniques for recording visual evoked potentials from multiple sclerosis patients. They can be shown initially to suffer the selective loss of their X fibres (*The Evoked Potential*, edit. by Desmedt, J., Oxford University Press, in the press), and they complain, not of the loss of detailed vision, but that they cannot tell the position of an object if it is moving.

Hard wiring in the cortex?

The mechanistic approach remarked by Wall at the BRA meeting is at its most impressive in the visual cortex, where, as Wall pointed out, the beginnings of abstraction are to be seen in the existence of cells which respond selectively to lines of a given orientation. A. J. Movshon (Cambridge University) briefly sketched the history of the controversy which still exists over the part played by postnatal experience in determining orientation selectivity, concluding with some arresting recent evidence in favour of it.

Movshon has followed up the experiments of Pettigrew and Blakemore on the reversal of cortical ocular dominance as a result of suturing first one eye and then the other eye of kittens during the sensitive period. By micro-electrode recordings across the cortex

More than meets the eye

by Miranda Robertson

The Brain Research Association Summer School, held in Cambridge on September 22-24, was followed by the Annual Meeting of the Institute of Biology, on the Physiology of Vision, in London on September 25 and 26.

THE dominant theme of both meetings was the interpretation of brain function in terms of the anatomy, physiology and psychophysics of its sensory systems. Patrick Wall, introducing a session on receptor systems at the BRA, remarked on a recent trend towards explaining perceptual phenomena purely on the basis of receptor mechanics, which he identifies as a resurgence of mechanism, traceable to Mountcastle at Johns Hopkins.

Photoreceptor interactions

The success of that approach at the sensory periphery was vividly illustrated by Trevor Lamb (Cambridge University), who explicitly related established psychophysical phenomena such as Weber's law and the Stiles-Crawford effect to the results of intracellular recordings from cones in the turtle retina (Baylor and Hodgkin, *J. Physiol., Lond.*, **242**, 729; 1974 and Baylor and Fettiplace, *ibid.*, **248**, 433; 1975). His concluding report was on electrical coupling between photoreceptors which at first sight seems

counter-adaptive since it degrades visual resolution. A prominent effect, and perhaps the function of such coupling is to reduce the intrinsic dark noise which apparently results from random opening and closing of the light-sensitive ionic channels in the photoreceptor membrane (Simon *et al.*, *Nature*, **256**, 661; 1975).

Lamb and his colleagues now have evidence in support of the notion that noise level in a single receptor depends on the extent of coupling to other cells. Very noisy cones turn out to have narrow receptive fields, whereas quieter ones respond to stimuli over much broader areas. Quantitative studies based on the degree of noise reduction are now under way to elucidate the pattern of coupling.

The question of receptor interactions arose again at the meeting of the Institute of Biology, where John Scholes (Kings College London) presented evidence for systematic (and probably antagonistic) interactions between red and green and green and blue cones in the retinae of rudd and goldfish, where the different photoreceptors can be distinguished morphologically. The same pattern of interaction is reiterated in the bipolar and ganglion cells fed by the photoreceptors; which makes it all the more fascinating that embryologically, the photoreceptor and its bipolar and ganglion cells all seem to have the same

of a series of these animals at different times before and after suture, he was able to follow the expansion and contraction of the columns as first one eye and then the other took control.

That process is not controversial, and has actually been photographed by D. Hubel (Harvard University) who showed some amazing slides of coronal sections of monkey visual cortex stained by the injection of labelled amino acid into one eye. The zebra stripes formed across the cortex by the ocular dominance columns were caught in the act of reciprocal contraction and expansion as a result of suture reversal, leaving no room for doubt about what was going on.

The disagreement arises over orientation selectivity, which Movshon and his associates claim is influenced by visual experience and Hubel and Wiesel claim is innately specified. Movshon's evidence comes from recordings of a few cells in reverse sutured kittens that could be stimulated from either eye. Such binocular cells in normal cats invariably have the same orientation selectivity for stimuli from right and left eyes. In the reverse sutured kittens, however, Movshon found a few binocular cells, presumably in the process of changing their ocular allegiance, which seemed at the same time to be changing their orientation preference. These cells were selective for different orientations when stimulated through the different eyes.

While that would seem to be compelling evidence for plasticity under the positive influence of experience in the cat, Hubel has begun to test the effects of stripe-rearing (in which visual experience is limited to bars of a single orientation) in monkeys and (in the one satisfactory specimen so far) has found no effect on the columnar pattern of orientation selectivity of cortical cells. Challenged by Movshon, he could offer no explanation for the discrepancies; nor could Movshon explain recent failures to replicate stripe-rearing results in cats.

Perceptual problems

Another embarrassment for visual neurophysiologists emerges from psychophysical experiments on stereopsis described by J. P. Frisby (University of Sheffield). According to the neurophysiology, stereopsis is mediated by binocular, orientation-selective cells which have a marked maximum response where the stimuli in either eye have a specific horizontal disparity on the retina. Frisby has tested depth perception in man (two men, himself and one other) using an adaptation of the Julesz random dot stereogram made with lines instead of dots. He has found that the perceived depth is a function of the length of the lines

Assessing prospects for Spacelab

from John Gribbin

A FEW months ago a series of experiments were flown on board NASA's CV-990 'flying laboratory' to simulate an orbital mission by the European Spacelab which is to be flown on the Space Shuttle during the 1980s. Some of the first scientific results from this ASSESS mission are presented in a series of papers commencing on page 649 of this issue, but the other lessons learned are also of great interest.

The joint ASSESS mission illustrated that a low-cost programme with a low level of preparatory requirements, testing and documentation can operate successfully under the proper management. Not only was the ASSESS mission itself fairly cheap (by space agency standards); it provided every indication that low-cost projects can work well when the real Spacelab gets off the ground, which must be encouraging news for many of the research groups working within tight budgets to try to take advantage of the opportunities which will be provided by the next generation of manned spacecraft.

And such aircraft simulations may have a significant role to play in developing instrumentation for the next generation of unmanned spacecraft as well. The ASSESS flights included an experiment from the Laboratory for Atmospheric and Space Physics (LASP) of the University of Colorado, a scanning two-channel spectrometer

which covered the wavelength range 270–650 nm and was a prototype of the ultraviolet spectrometer which LASP expects to fly on the forthcoming Pioneer Venus orbiter spacecraft. The mission provided a far better opportunity to sort out bugs in the system than any ground based operation, as well as producing valuable observations of Venus.

But ASSESS proved that there will be real problems in the practical operation of a flying laboratory. Human engineering of instrument control is necessary, as is a near real time high quality visual display of recorded data to confirm to the operator that successful measurements are being made. One clear result emerged from the human side of ASSESS. The best results come from operators who are trained scientists, understand the equipment and can use a soldering iron effectively on the spot to overcome the troubles they have diagnosed. There will, it seems, be no retreaded test pilots on the Spacelab, only a professional astronaut-pilot and the professional scientist-operators.

A second mission is now planned. NASA has indicated that the CV-990 will be available in October/November 1976, which would allow time for the data collected to be usefully incorporated into the final stages of the development of Spacelab.

used, a result which defies explanation within the current physiological paradigm.

No satisfactory physiological paradigm has in any case yet been proposed for perceptual phenomena which depend on activity beyond the primary visual cortex, a point implicit in the title to which Stuart Sutherland (University of Sussex) addressed himself: "There's more to vision than meets the eye." Sutherland believes in the use of computer programs as a testable way of representing how feats such as human visual perception might be achieved, and the first lesson to be learned from such programs is the enormous amount of knowledge and past experience people bring to bear on seeing things (consider the difference between a layman and a trained histologist, looking at a microscope slide). The lesson from the current lumbering knowledge-based computer vision programs however seems to be that brains have some way of leaping to global conclusions while computers are still creeping along line by line. □

Protoplasts at Nottingham

from E. C. Cocking

The 4th International Meeting on Yeast and Other Protoplasts was held at Nottingham, UK on September 8–12. The proceedings will be published by Academic Press.

THIS was one of the rare occasions when workers on bacterial, fungal and higher plant protoplasts came together to exchange viewpoints. As a result it was possible to compare the properties of protoplasts from both eukaryotic and prokaryotic systems; and for many of the participants this was the major attraction.

Enzymatic proceedings for the degradation of the cell wall, resulting in protoplast release, are now largely standard procedures; and, although the enzymes used for isolation differ in the various systems, the influence of the exact nature of the cell wall was

central in all the discussions of protoplast isolation. The bacterial membrane was shown by R. E. Marquis and T. R. Corner (Rochester University, New York) to be a remarkably extensible structure, while the membrane surrounding fungal protoplasts attracted the attention of D. Kerridge *et al.* (Cambridge University) to ascertain whether difference in chemical composition of plasma membranes, from different growth stages in the growth cycle, could be correlated with differing sensitivities to polyenes.

The activity of the plasma membrane in the synthesis of a new cell wall around isolated protoplasts was described in detail for all three protoplast systems. The induced, heritable, condition of wall-less-ness in bacteria was shown not to be due to alteration in the DNA. No comparable stable L forms have been found to arise from fungal protoplasts, or from higher plant protoplasts. But Y. Meyer *et al.* (Heidelberg University) described special conditions under which higher plant protoplasts regenerate a non-rigid, polysaccharide containing, "pseudo-wall". The photosynthetic activity of plant leaf protoplasts was very lucidly described by G. E. Edwards *et al.* (University of Wisconsin). It is readily possible to compare the photosynthetic activities of protoplasts isolated from C3 and C4 plants. Indeed, such protoplasts are more useful than isolated chloroplasts for certain photosynthetic studies, since enzymes of the cytoplasm, peroxisomes and mitochondria may be involved in carbon metabolism during photosynthesis.

As might be expected, great interest centred on the activity of plasma membranes in the fusion of isolated protoplasts. Fusion of bacterial protoplasts is still neglected; work on the polyethylene glycol induced fusion of fungal protoplasts, is however, actively continuing, and L. Ferenczy *et al.* (Szeged University) and J. Anné (Louvain University) and J. F. Peberdy (University of Nottingham), were able to show how fusion was expressed by heterokaryon formation between nutritionally complementing strains. Until recently, the only means of hybridisation in plants was by sexual crossing; E. C. Cocking (University of Nottingham) surveyed the ever increasing momentum of work on an "alternative to sex" which involves the induced fusion of somatic plant protoplasts, and, following adequate selection and culture, the regeneration of hybrid plants; the importance of combining this somatic hybridisation with the sexual genetics of higher plants was highlighted. Following the report earlier this year of the induced fusion of yeast protoplasts with hen erythrocytes, con-

siderable interest was aroused by the report of M. R. Davey and J. B. Power (University of Nottingham) of ultrastructural studies which showed that the induced fusion of the yeast plasma membrane with that of higher plant protoplasts takes place within uptake vesicles, following treatment of mixtures of these protoplasts with polyethylene glycol.

F. E. Young *et al.* (Rochester University) showed how the bacterial surface plays an extremely important role in the uptake of DNA and adsorption of viruses. In the eukaryotic fungal and higher plant systems comparable studies are at a much earlier stage of development, and there are many technical difficulties still to be resolved. It was encouraging, therefore, that D. Hess (Hohenheim University) was able to show that there is a considerable enhancement of DNA uptake when the DNA is fed as a calcium phosphate complex. Also encouraging were reports from several laboratories that polyethylene glycol may be a useful agent in attempts to establish endosymbiotic associations between higher plant cells and microorganisms *in vitro*. Those more physiologically orientated workers, interested in cell fractionation, noted with interest the report of T. Boller *et al.* (ETH, Zurich) of the use of the polybase, DEAE-dextran, for the isolation of vacuoles by the lysis of yeast protoplasts.

There is no doubt that this meeting fulfilled a long felt need for greater contact between those working on prokaryotic and eukaryotic systems. When the next International Meeting is held in Szeged, Hungary, in 1978 it is intended to extend further this induced fusion of protoplast disciplines.

Problems in the derivation of mRNA

from a Correspondent

The third Arolla workshop on the formation of messenger RNA in eukaryotic cells was organised by Klaus Scherrer at Arolla, Switzerland from September 2-6.

As on the two previous occasions, the main focus was on mRNA synthesis, but related topics were included. The subject matter was therefore gene expression in the round.

The meeting opened with reviews of chromatin structure and the characterisation of nonhistone proteins. Despite universal agreement that chromatin has a beaded structure, containing discrete protein clusters, there is still considerable doubt both as to the organisation of the clusters and on the relationship

between the histones and DNA. Histone H1, which shows microheterogeneity and a varying mass ratio to DNA, is not integrally involved in the structure of the beads, which appear to be octamers containing two molecules each of histones H2A, H2B, H3 and H4. The authenticity of reconstituted preparations of chromatin remains in some doubt, since they do not generate the array of fragments containing multiples of 200 base pairs of DNA which is characteristic of mildly digested native chromatin. Whether reconstituted preparations can serve as accurate templates for transcription *in vitro* remains controversial.

The nonhistone proteins comprise a dauntingly large number of species which vary in molecular weight from less than 10,000 to more than 200,000 daltons. There was no indication of any hope that the problem of defining these proteins is nearer solution. The observation that 20% of the proteins bound to DNA in low salt are removed below 0.2 M and 20% above 3 M may help to explain conflicting views on the metabolic stability of nonhistone proteins. Progress has been made in identifying increasing numbers of prominent nonhistone protein components, including DNA ligase, DNA polymerase, histone kinase, histone methylase, actin, myosin, tropomyosin and α and β tubulins. But while this is valuable information in its own right, we cannot seriously hope to identify the putative regulatory proteins by a process of elimination.

Discussion of satellite DNAs *per se* gave the impression that progress in this area is now slow, perhaps inevitably, since the structure of the satellites is by now understood quite well while their possible functions are much less amenable to investigation. But a satellite-like structure of small scale tandem repetition has been observed in the nontranscribed spacer of ribosomal DNA, which displays microvariation in length. One possible function for the spacer in this system may be to help maintain the homogeneity of transcribed DNA sequences by increasing the frequency of unequal crossing over. Another tandemly repeated DNA sequence on which rapid progress has been made is, of course, the histone DNA. There appears to be a basic repeat unit which contains the sequences for all five histones, separated by short spacer regions. Whether a single precursor for all the histones is transcribed is not known. Progress with both rDNA and histone DNA has clearly received a tremendous boost from the successful cloning of the DNA by means of bacterial plasmids.

Bridging the gap between DNA organisation and chromatin structure on the one hand and on the other the

characterisation of the primary transcription product, there was a summary of recent electron micrographic observations on the active interphase chromatin of *Drosophila* nurse cells. This work has generated the first description, in these terms, of nonribosomal transcription units. In most cases, when the lengths of RNP fibres were plotted against distance along the DNP axis, a clear correlation extended over lengths averaging 3.2 μm . One appealing interpretation of these results is that each observed transcription unit is equivalent to a single cistron as defined by genetic analysis, with an apparent average length of 6 μm . These results contrast with biochemical observations of much smaller nuclear RNA molecules, a paradox whose resolution may help define the derivation of mRNA.

The existence of a giant nuclear precursor of mRNA remains controversial. Work on duck erythroblasts, mouse Friend cells, hen oviducts and L cells was reported; but there is no clear consensus on the characteristics of any precursors. The failure of ten years of effort to solve this problem suggests strongly that new techniques may be needed, perhaps for example the use of plasmid clones of appropriate sequences. Work in one system stands out, however; it was reported that only 20–25% of the total 75S product of Balbiani ring 2 of *Chironomus* salivary glands ever reaches the nucleoplasm and only 5% enters the cytoplasm. If this does not merely reflect the sickness of explanted glands, it would suggest a powerful processing component in gene expression.

In a session devoted to the ends of eukaryotic mRNA molecules, some possible functions emerged for 3' poly(A) sequences and 5' methylated caps. If the length of poly(A) on globin mRNA is reduced to less than 40 residues, its decay after injection into oocytes is accelerated. Decay is very rapid when the length is less than 15 residues. The validity of this observation is supported by the fact that during the later stages of reticulocyte maturation the length of the poly(A) of the mRNA that can be recovered remains a constant 40–50 residues, despite a net fall in the amount of mRNA per cell. Viral mRNAs which normally are capped require methylation of the 5' terminal guanine for translation in the wheat germ system. In this system methylation is required for formation of the initiation complex, and from this a 35 nucleotide 5' terminal fragment can be isolated following treatment with ribonuclease. Picorna viruses, which normally are not capped, are not translated in this system and are translated without methylation in others.

Much progress has been made in sequencing studies. Partial sequences of several purified poly(A)-containing mRNAs now are available; in several cases it is clear that there is a significant length of nontranslated RNA at each end, longer at the 3' end. Sea urchin histone messengers also contain a nontranslated region. Rabbit α and β globin mRNAs and a mouse immunoglobulin L chain mRNA contain a 3' terminal sequence which suggests the existence of two hairpin loops which may or may not be stable *in vivo*. If the loops are present, these three messengers contain the same short sequence along the spine of the molecule. Hen ovalbumin mRNA does not contain this sequence. But the tetranucleotide adjacent to the poly(A) moiety is the same in all four messengers; this might be part of signals concerned, for example, with termination of transcription or polyadenylation.

The inherent tendency of hnRNA to form aggregates makes doubtful many of the conclusions based on fractionation by means of affinity columns, since these are often operated under conditions likely to promote aggregation, and so molecules with no affinity might be aggregated with those that have and thus be retained. A promising approach to the structure of hnRNA appears to be the analysis of the smaller sequences obtained by fingerprinting T_1 digests of total hnRNA and analysis of the small (3%) residue which is resistant to ribonuclease A. Sequence analysis of the ribonuclease-resistant hairpins suggests that many may have the same or a similar sequence. This family of sequences has some 10^5 members, each perhaps 150 bases in length, and should correspond to something less than 1% of the mammalian genome. A fingerprint pattern containing some characteristics of the ribonuclease-resistant RNA is obtained from both the hnRNA and mRNA which hybridise with DNA at very low C_{ot} values. There were indications of a relationship between the RNase-resistant hnRNA hairpins and the S1-resistant foldback loops of DNA. The distribution in CsCl gradients of the DNA sequences complementary to hnRNA hairpins is different from the bulk DNA distribution, which would be consistent with some clustering of these sequences in DNA.

Since no enzymes which cleave RNA are known in eukaryotes attention was focused on those found in bacteria, where it seems that several different classes of recognition process are involved. Five hexanucleotide sites on RNA cleaved by RNase P are all different. And mutational changes in different parts of the tRNA precursor affect its processing; some of these are near the cleavage site, some are in the

complementary part of the molecule, and some are quite remote. On the other hand, the known 5' termini of T7 RNA fragments all have very similar sequences. One general point of obvious importance is the observation that hairpin loops are invariably implicated in bacterial processing reactions. A rather striking observation is that RNase D (=Q=III) can cleave 45S ribosomal precursor to yield a molecule sedimenting at 28S; however, characterisation of the product clearly is necessary before this can be interpreted. A feature of this enzyme is that it preferentially cleaves at specific sites in low salt, but preferentially solubilises double-stranded RNA in high salt; this reinforces the view that the products of its action must be carefully characterised. □

Dale centennial celebrations at Cambridge

from L. L. Iversen

The Sir Henry Dale Centennial Symposium—Post-synaptic Actions of Neurotransmitters was held in Cambridge on September 17–19.

In the days when Sir Henry Dale made his pioneering contributions to the understanding of the actions of histamine, adrenaline and acetylcholine (ACh) on various tissues including those of the nervous system, he deliberately avoided the use of the term "receptor", then used in a purely operational sense. Such reticence is no longer necessary, as was amply demonstrated by the up-to-date reviews of drug-receptor interactions presented at the symposium.

The highest development of such studies was described by J. P. Changeux (Pasteur Institute, Paris), reviewing the work of his group on the purification and characterisation of the nicotinic cholinergic receptor protein from excitable membranes of the electric organs of fish. Changeux described a model for the action of the ACh receptor which postulates the existence of the receptor in three possible states: resting, activated and—after prolonged exposure to ACh or a related agonist—a desensitised condition. Desensitisation can be demonstrated *in vitro* using membrane fragments exposed to carbachol, and results in binding of ACh and other agonists with unusually high affinity, but without transduction into a change in membrane sodium permeability, as in the normal transition from resting to activated states.

Remarkable new refinements in the neurophysiological study of ACh at the

neuromuscular junction were reported by Sir Bernard Katz (University College, London) and S. Kuffler (Harvard Medical School). Katz described how statistical analysis of the increased muscle membrane noise generated on exposure to ACh has shown the precise characteristics of the changes in membrane conductance elicited by ACh in individual membrane ionic gates or channels. Kuffler described work by his group on snake muscle, in which it is possible to apply measured amounts of ACh directly to the endplate areas of muscle membrane from which the nerve terminal has been removed by microdissection. They have established that less than 10,000 molecules of ACh are needed to mimic the effects of one quantum of transmitter normally released by the nerve terminals (several hundred such packages are released by each nerve impulse).

A. S. V. Burgen (National Institute for Medical Research, London) described rapid progress in characterisation of muscarinic cholinergic receptors. The binding characteristics of labelled antagonist drugs to muscarinic receptors in smooth muscle or brain correspond well to those predicted from previous pharmacological experiments, but those of agonists seem more complex. Graphs of agonist binding followed non-linear Hill plots, suggestive of complex cooperative interactions with the muscarinic receptor sites, or, more probably, of the existence of more than one category of agonist binding site. The latter possibility is in accord with the earlier findings of Spero and Burgen, that agonist effects on ion fluxes and contraction in smooth muscle are not always parallel. When a covalent alkylating reagent for muscarinic sites is used, N-propylbenzilylcholine mustard, the muscarinic receptor molecule in smooth muscle can be identified as a polypeptide with a molecular weight of 85,000.

P. Greengard (Yale University) reviewed evidence that the post-synaptic actions of ACh at muscarinic receptors and of other transmitters, notably noradrenaline and dopamine in the brain, may be mediated by changes in the concentrations of cyclic AMP or cyclic GMP in the post-synaptic cells as a result of activation of a transmitter-sensitive adenylate or guanylate cyclase in the synaptic membrane. Recent work supports the hypothesis that cyclic nucleotides may produce synaptic potentials by activation of a protein kinase that in turn alters the level of phosphorylation of proteins in the synaptic membrane and consequently the ion permeability characteristics of the cell. In synaptic membranes from brain, cyclic AMP activated the phosphorylation of a few specific membrane proteins, some of which have

been purified. In a simpler system, the turkey red blood cell, which responds to catecholamines by changes in ion permeability through a cyclic AMP mediated β -adrenoceptor mechanism, it was possible to show a good correlation between the extent of increased phosphorylation of a specific membrane protein and the associated changes in intracellular cyclic AMP and ion fluxes caused by exposure to catecholamines.

Experiments on dopamine receptors in mammalian brain, using radioactively-labelled dopamine or the antagonist drug haloperidol as ligands, were described by S. Snyder (Johns Hopkins University). The data on the direct interaction of agonists and antagonists with CNS dopamine receptors complemented those of Greengard and others from studies of drug interactions with the dopamine-sensitive adenylate cyclase in mammalian brain. As with several other transmitter and drug receptors, there was evidence that dopamine receptors could exist in two stable configurations, one with a high affinity for agonists, and the other with lower affinity for agonists but a high affinity for antagonists.

D. Jenkinson and J. Black (University College, London) discussed the dual receptor systems that mediate adrenaline and histamine responses in the body, the α - and β -adrenoceptors, and H1 and H2 histamine receptors. The use of radioactively labelled β -adrenoceptor antagonists, such as alprenolol, allows the ligand binding approach to be applied here also. The possible interrelations between the two types of adrenoceptor remain tantalising but obscure; Jenkinson's own group has recently shown that β -adrenoceptor agonists could elicit changes in ion fluxes in isolated tissues only after a previous exposure to α -adrenoceptor stimulation.

G. Aghajanian (Yale University) described the work of his group on the neurophysiological characterisation of receptors for 5-hydroxytryptamine (5-HT) in mammalian brain. The actions of 5-HT on receptors located on the surface of the 5-HT neurones themselves are very potently mimicked by *d*-LSD and related hallucinogens, which thus cause a powerful inhibition of the firing of 5-HT neurones in the brain.

Surface bound antibodies on B lymphocytes and on mast cells have many similarities to the receptor macromolecules of excitable tissues, and M. Raff (University College, London) reviewed the work of his group on the unexpected lateral mobility of such ligand-binding proteins in the cell membrane. Recent fine structural studies of histamine release from mast cells throw new light on the mechanism of exocytosis in which cell membrane protein seems to be conserved by migration from

regions of contact between secretory vesicles and plasma membrane.

Finally J. Axelrod (National Institute of Mental Health) reviewed work by his group on the longer term changes that are initiated by transmitter molecules impinging on post-synaptic tissues. In adrenergic neurones and in the pineal gland the extent of synaptic stimulation controls the rate of synthesis or degradation of key enzymes in the biosynthesis of catecholamines or the pineal substance melatonin. The pineal gland in particular offers an elegant model system for studies of the rapid and complex changes that can occur in protein synthesis, enzyme activity and the sensitivity of the β -adrenoceptors to stimulation by catecholamines. Changes in receptor sensitivity leading to supersensitivity (with decreased stimulation) or subsensitivity (on prolonged stimulation) can occur in this tissue within a few hours and are associated with parallel alterations in the number of β -adrenoceptors detectable by radioactive alprenolol binding studies. □

Crystallographers in Amsterdam

from Olga Kennard

The 10th International Congress of Crystallography was held in Amsterdam on August 7-15.

AMSTERDAM in the heat wave, with flags flying, sunlight glittering on the canals and 1,500 crystallographers gathered for their 10th Congress—29 years after the foundation of the International Union of Crystallography and some 63 years since the beginning of X-ray crystallography. A young discipline—and even the disciples have hardly aged. The pace of the Congress was set by Paul Ewald, now 87, who not only gave a memorable discourse, but who, by his penetrating questions, made many a younger contributor re-examine his basic assumptions.

Crystallography is still full of excitement and experimentation. Experimentation even in scientific communication, which at Amsterdam meant great emphasis on poster sessions held in specially constructed booths complete with tables, chairs and blackboards—veritable psychiatric clinics! Altogether some 600 contributors opted for posters compared with 300 short oral papers. The sense of "discussions in corridors" prevailed in the booths as shown by the continuous and spirited arguments which otherwise so rarely develop in lecture rooms after short presentations.

Poster sessions were complemented

by invited lectures. Some such as Phillip Coppens's (State University of New York, Buffalo) review of the accurate determination of electron densities, drew together and made coherent sense from a scatter of individual exhibits and gave the necessary background and critical evaluation for the non-specialist. More of these link-lectures would ensure even greater effectiveness of the poster sessions at future Congresses.

The eight general lectures were all delivered with great style and high information content. Caroline MacGillavry's discourse on "Order and Beauty" continued the old crystallographic tradition of linking the two cultures. A. I. Kitaigorodski's (Institute of Elemento-Organic Compounds, Moscow) talk on "Interaction in molecular and non-molecular crystals and lattice dynamics" should perhaps be mentioned for its simplicity of approach, which set a good example, especially to the younger generation of computer-bred crystallographers juggling with too many variables. His definition of scientific theory: first rate if it can predict, second rate if it can forbid and third rate if it can explain "post factum", became a useful yardstick for the Congress.

There were 27 main topics covering all aspects of crystallography from perfect crystals to almost total disorder. Macromolecules, both globular and fibrous, were well represented, with an impressive exhibit of models, and considerable emphasis on the functional and evolutionary aspects. There seems to be an imminent breakthrough in virus structures and a particularly exciting account was given by John Champness (MRC Laboratory of Molecular Biology, Cambridge) on the structure of the disk of tobacco mosaic virus protein to 5 Å resolution.

It would be tempting for this rapporteur to discuss small biological molecules, for example the first phospholipid and membrane component structures (R. Mason, University of Sussex; S. Abrahamsson, University of Göteborg; and M. Sundaralingam, University of Wisconsin, Madison) but invidious if some fascinating compounds in the six other structural sections are neglected. The general impression was that crystallographers have now overcome their sense of guilt at the comparative ease with which structures can be solved and are turning their attention to a more fundamental interpretation of the results in terms of physicochemical properties, function or mode of action.

Not all structures yield to current techniques and one of the highlights of the meeting was the session on direct mathematical methods. H. Hauptman (Medical Foundation of Buffalo) set the

theme with a general talk which included the new quartet invariants—a true breakthrough! P. Main (York University) discussed the use of known chemical information and his matrix approach looks very promising.

B. Busetta (University of Bordeaux) applying these methods, reported the solution of perhaps the largest "small" structures to date with 116 and 126 light atoms in the asymmetric units of difficult, non-centric space groups. Rumour has it, however, that the Karles (Naval Research Laboratories, Washington) still keep the record, with a modification of valinomycin (156 atoms in space group P1). These new developments offer real promise to view, without recourse to heavy atoms, the structure of compounds perhaps as large as 3,000–5,000 daltons, at atomic resolutions.

An interesting feature of the exhibits was a structure-solving clinic using a minicomputer (G. Sheldrick, Cambridge University; E. Oeser, Technische Hochschule, Darmstadt). Sixteen apparently insoluble structures were submitted and six were actually solved and refined during the Congress. Need sponsors have any better proof of the value of international meetings!

A final word about the small community of Dutch crystallographers. They organised the Congress with imagination (the brass band of the Amsterdam Police instead of welcoming speeches!) and a friendly efficiency which ensured the highest possible satisfaction quotient—both scientific and social—for all participants. □

Vaccination against fertility

from a Correspondent

The Third International Symposium on the Immunology of Reproduction was held in Varna, Bulgaria on September 21–25. It was supported by the Union of Scientific Workers in Bulgaria, the G. Dimitrov Agricultural Academy, the Bulgarian Academy of Sciences, the Ministry of Health in Bulgaria and the World Health Organisation. The proceedings will be published by the Bulgarian Academy of Sciences.

THE proceedings in Varna revealed good prospects for an anti-fertility vaccine, potentially invaluable in the battle against world overpopulation. Of particular interest were the initial findings of G. P. Talwar (All India Institute of Medical Sciences, New Delhi) who injected a few women with the specific portion (the beta subunit) of human chorionic gonadotropin

conjugated with tetanus toxoid. The antibody titre to the gonadotropin rose to high levels which were maintained for more than a year, and the antibody was shown to inhibit the biological activity of the gonadotropin, which plays an essential role in pregnancy. In one case, a booster inoculation was given when the antibody titre fell and this was followed by a return to former levels. Tests on a wide range of bodily functions provided no evidence of any undesirable side-effects of the treatment. The women had previously requested surgical sterilisation and menstrual cycles continued throughout the period of observation. Similar studies to Talwar's are being initiated in several institutions in Europe and the Americas, so that thorough assessment of the safety of the method should be accomplished in the near future. Large-scale clinical trials will follow if indications are favourable. In spite of Talwar's apparent breakthrough, however, detailed studies are continuing in various laboratories on the synthesis and biological activity of amino acid chains representing parts of the non-homologous region of the beta subunit which could prove highly specific antigens. The possibility of immunisation with other specific placental proteins is also being pursued actively, chiefly with components identified as SP1 and PP5.

Probably the largest single topic of the symposium had to do with the antigenic structure of spermatozoa and their immunological potential in both the male and the female. In the human male the concern was primarily with infertility associated with anti-sperm antibodies in the circulation, and with the risk of autoimmune damage in vasectomised men. The impressively extensive use of vasectomy in India was described by S. S. Rao (Institute for Research in Reproduction, Bombay) who noted that many subjects were found to have high titres of circulating antibody apparently without serious consequence. The prospects of developing a contraceptive vaccine for males as an alternative to vasectomy has been improved by the use of adjuvants with less drastic local effect than Freund's adjuvant. With the female the emphasis is on the control of fertility by immunisation with spermatozoa or specific sperm antigens, such as hyaluronidase, acrosin, LDH-X and antigen T. Progress in this field was usefully reviewed by W. R. Jones (Flinders University of South Australia, Adelaide). Antibodies against these antigens do not cross-react significantly with somatic tissue antigens, although human acrosin is very similar in amino acid composition to pancreatic trypsin. Some depression of fertility is achieved by active immunisation but the results are not yet

satisfactory. Curiously enough the reduction in fertility produced by anti-LDH-X antibodies is owing mainly to embryonic death during cleavage and implantation. The fact that sperm-agglutinating but non-immobilising sera could prevent sperm penetration through cervical mucus in an *in vitro* test was reported by B. Boettcher (University of Newcastle, New South Wales). S. Shulman (New York Medical College) noted the occurrence in cervical mucus of sperm-immobilising antibodies active in the absence of complement. S. Isojima (Hyogo Medical College, Nishinomiya) described an improved microtechnique for detecting sperm-immobilising antibodies in cervical mucus. The risks involved in the use of placental hormones and sperm antigens were considered critically by K. S. K. Tung (University of New Mexico, Albuquerque).

The foetus as a homograft received its share of attention, the feeling clearly being that the reasons for the lack of foetal rejection are still poorly understood. But further support was provided for the idea that genetic dissimilarity favoured implantation. □

Charting the cell cycle

from M. Vicente

The Third European Workshop on the Cell Cycle sponsored by the European Cell Biology Organisation was held in Edinburgh on September 23-25.

SIMPLE systems still seem to be leading the race for the understanding of the events constituting the cell cycle. Although the majority of the papers dealt with eukaryotic systems, the most interesting results were reported from studies of prokaryotes or relatively simple eukaryotes such as yeast and the slime mould *Physarum polycephalum*. These organisms share the property of being either single cells or plasmodia in which the life history of a growing individual is not heavily disturbed or dependent on the presence of other individuals or their metabolic products. Moreover all of them are suitable for biochemical and genetical studies.

M. Masters (University of Edinburgh) has produced strains of *Escherichia coli* in which a duplicate copy of the chromosomal origin of replication is carried on a plasmid. Such strains have a significantly reduced number of chromosomes per cell mass and also divide at a proportionally larger size. These properties are consistent with the idea that there is a fixed amount of some substance required for the initiation of DNA replication at the chromo-

some origin and that the presence of extra copies of this origin results in competition between the chromosome and the plasmid for initiation at each mass doubling.

Three communications by P. Thuriaux *et al.*, P. Fantes and P. Nurse (University of Edinburgh), gave a new view of the cell cycle in the fission yeast *Schizosaccharomyces pombe* obtained from the study of mutants in which progression through the cycle is blocked or altered at different stages. There is a close similarity between the cell cycle in *Saccharomyces cerevisiae* and that in *S. pombe* as described by Thuriaux *et al.* Both cycles are in turn very similar to the *E. coli* cycle summarised at the meeting by W. D. Donachie (University of Edinburgh). The cycles in the three species have two independent pathways, one involving chromosome replication, both of which are required for the normal progression of the cell towards division. There is also evidence suggesting that the pathways comprise several sequentially dependent reactions.

Homeostatic control of cell size in *S. pombe* was observed by P. Fantes studying a thermosensitive mutant blocked at a stage before nuclear division at the restrictive temperature. The treatment does not seem to disturb cell growth in other ways and allows cell elongation to proceed. In these circumstances a negative correlation between the length of a cell at division and the duration of the following cycle is observed once the cells are shifted back to the permissive temperature. Some of the processes leading to division are more dependent on time than on size, however, as no matter how long the cells become before the temperature release they always require a minimum time before they can divide.

That initiation of DNA synthesis can be controlled by size while nuclear division is controlled by time was suggested by Nurse when interpreting his observations in a *S. pombe* mutant in which mass at division is half the wild type value and DNA synthesis is displaced to a later stage of the cycle while timing of nuclear division remains unchanged. The simultaneous functioning of timing and size controls is one more aspect in which the cell cycle in *S. pombe* is analogous to that of *E. coli*.

Replicating DNA fibres of *S. cerevisiae* have been made visible by autoradiography, after pulses of radioactive uracil, by D. H. Williamson and T. D. Petes (National Institute for Medical Research, London). They find that DNA replication proceeds bidirectionally in most of the replicons starting from several replication origins in each fibre, as in other eukaryotes. Therefore most of the replicons seem to initiate synthesis very early in the S period as

replication becomes resistant to inhibition of protein synthesis once the S period has started.

A quite different replication pattern is present in *Physarum polycephalum* in which several protein-dependent initiation events are detected by cycloheximide inhibition. Studying replication of DNA during the step that takes place 30 min after mitosis, F. Haugli (University of Tromsø) has isolated, after short pulses of ³H-thymidine, 7S DNA fragments very similar to the *E. coli* Okazaki pieces. These fragments are gradually chased into longer intermediates by a process that closely resembles the joining by ligase in *E. coli*.

Both R. Braun and V. M. Vogt (University of Berne) and H. W. Sauer *et al.* (University of Konstanz) suggested that the DNA that codes for ribosomal RNA in *Physarum* is contained in a structure that resembles morphologically a bacterial plasmid. In addition Braun and Vogt have found that replication of this rDNA occurs at random during G₂, a mode of replication that is consistent with that found in plasmids.

Reports on *Physarum* presented at the workshop show that studies on this organism are in a state comparable with that of *E. coli* in the early 1960s—that can be taken optimistically or pessimistically depending on how one views it. □

A hundred years ago

SIXTH REPORT OF THE SCIENCE COMMISSION

THREE times within the last twelve years a Royal Commission has reported on the science teaching of our higher schools. In 1864 the Public Schools Commission announced that from the largest and most famous schools of all it was practically excluded. In 1868 the Endowed Schools Commission declared that the majority of school teachers had accepted it as part of their school work. The Science Commissioners of 1875, in their Sixth Report, on Science Teaching in Schools, testing this statement by inquiry, reports that of 128 endowed schools examined by them not one-half has even attempted to introduce it, while of these only 13 possess a laboratory, and only 10 give to the subject as much as four hours a week. And this statement is curiously illustrated by the statistics of the recent Oxford and Cambridge School Examination, which show that out of 461 candidates for certificates from 40 first-class schools, while 438 boys took up Latin, 433 Greek, 455 Elementary Mathematics, 305 History; only 21 took up Mechanics, 28 Chemistry, 6 Botany, 15 Physical Geography.

Simulating experiments for Spacelab

In June this year a number of flights were made in a NASA CV990 aircraft to evaluate designs for experiments to be carried aboard Spacelab from 1980 onwards. Here five of the groups involved describe what they achieved. NASA and the European Space Agency recently decided to carry out another similar mission next year.

Measurements of ozone and minor atmospheric constituents

THE instrument flown was an absolute spectrometric radiometer for the spectral range $3\text{--}40\text{ cm}^{-1}$. Such an instrument on a space platform would be used to measure the cosmic background spectrum and to monitor atmospheric constituents. At aircraft altitudes the atmospheric emission prevents the first, and the scientific objectives set for the flights were therefore to explore the spectral assignments and concentrations of ozone and minor constituents of the atmosphere and in so doing to test developments of technique. Previous experiments had shown the need for improved techniques that would give a resolution of at least 0.01 cm^{-1} unapodised so that overlapping emission lines from different constituents are resolved, that would allow an interferogram to be recorded in no more than a few minutes because significant changes can occur in atmospheric conditions in such time intervals, and that would give measurements of emission in absolute terms in order to make possible quantitative estimates of constituents. The changes required in the instrumentation¹ to give these improvements were the introduction of a fast data acquisition system, the adoption of the polarised interferometric method both to suppress the effects of signal fluctuations and to allow continuous reference to a cooled black-body calibration source^{2,3}, and the incorporation of greatly improved germanium bolometric detectors (P. A. R. Ade and S. El-Atawy, personal communication).

At the altitude of the aircraft (up to about 39,000 feet) there was appreciable atmospheric water vapour. Nevertheless, most

of the spectra were recorded at an elevation of no more than 14° to give a long path for the minor constituents. The aircraft was, during most flights, close to the tropopause (high at that time of the year) and it would have been unproductive to take measurements over a range of elevation angles so as to give limb-scanning information on the vertical structure of the atmosphere (though a suitable input mirror system had been incorporated for this purpose). It was, however, essential to have a servo-controlled input mirror, taking its drive from the aircraft's inertial guidance system to maintain constant elevation during the recording of an interferogram.

The emission was continuously compared with that from a black-body cavity; to give absolute calibration two black-body cavities were used, one at ice temperature and the other at liquid-nitrogen temperature. More than 100 interferograms were recorded, and even though the analysis is not yet complete it is clear that the new techniques were successful. To illustrate this, Fig. 1 shows small parts of two of the emission spectra, relative to the ice black body. The interferogram for each was recorded in 8 min and the spectrum obtained covers the range $3\text{--}40\text{ cm}^{-1}$, of which only the part from 20.5 to 22.5 cm^{-1} is shown. The Fourier transform was linearly apodised to give a resolution of 0.02 cm^{-1} . One of the spectra is displaced upwards to avoid overlapping. Both were obtained at an altitude of 33,000 feet and at an elevation angle of 14° ; they were recorded successively. It can be seen that most features are reproduced in the two spectra. The positions of lines of possible constituents of the atmosphere are marked at the top of Fig. 1, as derived from theoretical calculations and laboratory measurements (J. W. Fleming, private communication).

Photography and photometry of the near infrared OH airglow

WE are able¹ to photograph the near infrared OH airglow, and the ASSESS mission allowed us to carry out: (1) horizontal parallax measurements of airglow features over a wide geographic range, using the plane's motion to generate a baseline; (2) photometry over a wide range in latitude and longitude to

Fig. 1 1-s exposure at 9:15 UT, June 18, 1975 at about 39,000 feet over Oregon.

study any geographical variation in intensity; (3) correlation studies of the brightness of OH bands between 690 and 840 nm for comparison with earlier work².

Our instruments were modified for aircraft use primarily by automating the repetitive measurements and incorporating image intensifier tubes to reduce exposure times, thereby minimising smear of photographs due to aircraft roll.

Three separate instruments were flown. (1) A 35-mm camera obtained exposures every 1 min of a $25^\circ \times 35^\circ$ area of the sky. A two-stage image tube with extended S-20 photocathode, 50-mm focal length input lens, and 720-nm cut-on filter, provided usable photographic densities in 1 s. (2) Colinear with the 35-mm camera an absolutely calibrated photometer viewed the central portion of the picture. An extended S-20 phototube preceded by a 7.5 cm $f/5$ telescope and an eight-position filter wheel with 20-s dwell time comprised the photometer. Four 10-nm bandpass filters were centred on OH bands at 690, 730, 790, and 840 nm, two filters were centred on non-airglow regions at 710 and 820 nm, one filter was identical to that on the 35-mm camera, and one position was opaque so that the dark current could be measured. (3) A 16-mm movie camera photographed another image tube with input lens and filter every 2 s, giving a continuous record of aircraft roll, as well as providing a motion picture of the passing airglow structures, tropospheric clouds, stars, and the Milky Way.

During the ASSESS mission 18 h of data (representing about 97% of the time suitable for airglow studies) were obtained. The entire mission of 14 flights has provided some 3.5 h of data per flight.

We have 2,500 35-mm frames (see Fig. 1), plus 45 h of photometer data, to analyse. With these data we will study the variation of parallax emission heights with geographical location and the relationship of OH patch or stripe size to emission height. The photometer will show any correlation between OH band intensity and geographical position, as well as the correlations between band intensities. By comparing photographic and photometric data, a correlation will be sought between type of structure and/or intensity with the height of the tropopause, magnetic and/or solar activity indices, local weather, and geographical features such as mountain ranges.

This work was supported by NASA and the European Space Agency.

Filter wedge spectroscopy in the region 3–6 μ m

SECTRA of Venus obtained previously in the region 1–6 μ m led to the identification of H_2SO_4 as the primary aerosol in its atmosphere^{1,2}. Identification depended on comparison of the detailed shapes of the calculated and observed absorption features. The ASSESS mission provided the opportunity to observe Venus at a different phase angle, providing additional data on the structure of its upper atmosphere. The chance also arose to observe IRC+10216, which has not been studied in this spectral region with an airborne telescope.

The instrument flown consisted of a continuously variable filter wedge spectrometer plus a liquid nitrogen-cooled InSb detector system. The bandpass of the spectrometer was from 2.8 to 5.6 μ m with roughly 1.5% resolution and it was rotated continuously while taking spectra. Signal processing used a standard phase-lock amplifier system referenced to the oscillating secondary mirror of the telescope. The spectrometer and detector were mounted at the focus of the Meudon 30-cm telescope. The overall system bandpass, including the effects of the Mylar window, was approximately 3.5 to 5.0 μ m.

Unfortunately the aerodynamic loading on the Meudon telescope was so severe as to require that a Mylar window be installed over the cavity. This compromised our data in three ways: (1) Mylar has a rather broad absorption feature centred at roughly 3.4 μ m, just in the best region for studying H_2SO_4 on Venus; (2) a large offset signal due to the window was observed; and (3) condensation on the window gave some signal attenuation, though this was a minor problem in this spectral region. Nevertheless, spectra were obtained of Venus, IRC+10216, and the Moon for calibration and are being analysed.

Airborne television observations of airglow clouds in the near infrared

AN image iscocon intensifying television system was flown to make a survey of the size, geographical distribution and frequency of occurrence of airglow clouds in the near infrared. Peterson and Kieffaber¹ have published photographs of cloud-like structures identified as OH airglow, taken at low elevation angles and with exposures of several minutes, on clear nights in New Mexico. The aim of our experiment was to establish whether airglow structures detected with the image intensifying television could be used as tracers of winds in the upper atmosphere.

The television system can detect very faint light signals (it provides at least two orders of magnitude intensification), with the option of integrating the image inside the television tube for periods from 1/25 s up to several seconds. This instrument could therefore detect and record airglow emission structures rapidly and so give good spatial and temporal resolution. Furthermore, the use of an aircraft as an observation platform makes it possible to eliminate most of the interference from meteorological clouds.

The television camera was primarily positioned looking out at 60° to the horizon, but on two flights it was situated at a 15° window. The camera had a 30° field of view. The long wavelength cut-off at the television tube was ~ 900 nm, with peak response at ~ 600 nm. A Wratten filter with short wavelength cut-off at 670 nm was placed in front of the camera lens. Peterson and Kieffaber² made observations of airglow clouds

Fig. 1 Airglow clouds looking east from an altitude of 39,000 feet on June 18 at 0930 UT (0122 LT), latitude 45°, longitude 122°W. The picture was obtained by integrating over seven television fields, that is, for 0.28 s.

at a 15° window on the same side of the aircraft throughout the mission.

We found that well defined cloud-like structures could be observed easily with the camera only from the low elevation (15°) window (see Fig. 1). The atmosphere was not sunlit below about 400 km at this position, thus excluding the possibility that these structures are noctilucent clouds.

Assuming that the aircraft speed (~ 250 m s⁻¹) is likely to be much greater than upper atmospheric wind speeds at middle latitudes, we can estimate the altitude (80–85 km) and horizontal dimension (~ 20 km) of individual bright patches of airglow.

Airglow viewed through the 60° window was diffuse, and small scale structure was not easy to identify. There were, however, variations in intensity over the television field of view, particularly when well defined structures were visible at lower elevations through the image intensifiers of the cameras of the New Mexico group. Identification of individual clouds was complicated by the aircraft roll during the longer integration times (1 or 2 s) needed at the high elevation window because of lower airglow intensities. These lower intensities indicate that the thicknesses of the airglow structures are small compared with horizontal dimensions. The general airglow brightness, seen from the 60° window, varied from day to day and from place to place; we are making a separate study of these variations from the television records.

Far infrared observations of dark cold clouds and H II regions

WE present here a brief description and preliminary results of our airborne far infrared experiment (see ref. 1). At the focus of a 30-cm open-port Cassegrain telescope was a Low-type germanium bolometer, NEP of 3×10^{-14} W Hz^{-1/2}, following a four-filter set of bandwidths, respectively, 31–38 μm, 47–67 μm, 72–94 μm and 114–196 μm. Cold diaphragms from 1.57' to 6.3' were actually used². The secondary mirror was wobbling at 37 Hz, with a typical beam throw of 9', and scanning in both *x* and *y* was possible up to 30' × 30'. The stability of the system was better than 1' and was as low as 15'' during steady parts of the flights. Tracking was done by means of the star video signal (from a Nocticon tube), which was electronically processed and looped on the torque motors of the gyro-stabilisation. A PDP-11 computer was used for on-line visualisation of digitised maps.

Calibration was carried out seven times on Venus, but unfortunately not for all the flights reported on here. Significant and variable 'sky noise' (of up to 20 times the detector noise) meant that only some of the data is really usable; we therefore made systematic measurements on this 'sky noise' (to be published).

Table 1 Flux intensity in 10^{-23} W m⁻² Hz⁻¹

Source	114–196 μm	72–94 μm	46–67 μm
W51	4.4 ± 0.5	16 ± 2	42 ± 4
M17	28 ± 8	—	—
ρ Oph	14 ± 4	—	—
S131	22 ± 6	—	—

The aim of the experiment was the detection and mapping at several wavelengths of dark galactic clouds. Four sources were studied: ρ Ophiuchus, S131, W51 and M17. At this early stage of the data examination, only the last two seem to show extension and structure. Table 1 summarises the fluxes computed for these four objects assuming, for Venus, a black-body temperature³ of 220 K, and a size of 19'. We can derive for W51 an equivalent black-body temperature significantly higher than that proposed by Harvey⁴, at least 100 K. As for M17, our values agree well with those of Hoffmann⁵, assuming that the source is extended and uniformly bright. Our studies of ρ Oph and S131 confirm the high degree of correlation between CO clouds and dark regions^{6,7}.

Operon structure of DNA transfer cistrons on the F sex factor

Reiner Helmuth & Mark Achtman

Max-Planck-Institut für molekulare Genetik, Berlin, West Germany

The operon structure of the tra cistrons on the F sex factor has been investigated using Mu-1 bacteriophage. Twelve tra cistrons comprise one polycistronic operon 15 × 10⁶ to 20 × 10⁶ daltons long.

GENETIC analyses¹⁻⁷ of transfer-deficient (Tra⁻) mutants of the F sex factor have revealed the existence and map order of thirteen *tra* cistrons on F as summarised previously^{8,9}. Electron microscopic analysis^{10,11} of DNA heteroduplexes made with Tra⁻ mutants, has resulted in a physical map that correlates with genetic assignments as shown in Fig. 1. The physical units are kilobases (kb), an abbreviation for one thousand nucleotide bases or base pairs. Throughout this article, right and left refer to the (arbitrary) orientation used in Fig. 1. The *tra* cistrons are clustered according to function in that cistrons between 62 and 79 kb are involved in F pilus synthesis while cistrons between 80 and 94 kb have other DNA transfer-related functions but are not necessary for F pilus synthesis. We believe that *traJ*, located to the left of all other *tra* cistrons, codes for a positive control protein, necessary for the production of all other *tra* cistron gene products; thus *traJ*⁻ mutants lack all the other *tra* gene products as demonstrated by genetic tests¹².

One of the *tra* cistrons, *traS*, lies between 80 and 89 kb (between *traG* and *traD*⁷). *traS* codes for the surface exclusion phenomenon wherein F-carrying cells are poor recipients (Sfx⁺) for conjugation with other F-carrying donor cells. *traS*⁻ mutants are still transfer-proficient¹⁰. Thus the wild-type F factor exhibits a Tra⁺ and Sfx⁺ phenotype. *traJ*⁻ mutants are Tra⁻ and Sfx⁻, whereas mutants in other *tra* cistrons are Tra⁻ but Sfx⁺. A few nonsense and frameshift mutants located to the left of *traS*,

are partially surface-exclusion-deficient and exert polarity on *traS* as if it were in the same operon². None of these putative polar mutants, however, lies to the left of *traK* (68–73 kb), so they are of little use for defining the operon structure of all the *tra* cistrons. The genetic properties of Tra⁻ deletion mutants³ indicated, however, that any polycistronic *tra* operon(s) must be transcribed from left to right. Accordingly, we initiated a search for absolute polar mutants mapping in each of the *tra* cistrons, to investigate their polarity on the other *tra* cistrons and thus to define the structure of the *tra* operon(s). Mu-1 bacteriophage has been found to insert itself randomly within *Escherichia coli* DNA¹³ and such Mu-1 insertions manifest (absolute) polarity on any cistrons lying distal to the Mu-1 insertion site¹⁴⁻¹⁸ in the direction of transcription by acting as a transcriptional block¹⁹. Indeed if all the *tra* cistrons between *traA* and *traI* were in one operon, the *traA*–*traI* operon would have a length of 15 to 20 × 10⁶ daltons and thus would be the largest bacterial operon yet described.

Isolation of Mu-1 insertion mutants

The information we have on *traS* predicted that we could separate Mu insertions into two classes on the basis of whether or not they were polar on *traS*. Mu insertions polar on *traS* would lead to an Sfx⁻ phenotype, whereas Mu insertions not polar on *traS*, because they were in a different operon or operator-distal to *traS*, would be Sfx⁺. The isolation of Sfx⁻ mutants, however, is technically difficult for the following reasons. Good recipient mutants (Sfx⁻) are at a growth disadvantage in a mixed population with Sfx⁺ wild type cells because of the repeated unidirectional DNA transfer from wild type cells to Sfx⁻ mutants which results in a relative dilution (contraselection) of the

Fig. 1 The physical map of F. All units given are in kilobases (kb) according to the results of Davidson *et al.*¹¹. IS represents the known locations of insertion sequences¹¹. The location of the *pif* cistrons which code for restriction of T7 and ϕ_{11} phages is according to M. Malamy (personal communication). The location of the *rep* cistron(s) which code for vegetative replication is according to Davidson *et al.*¹¹ while the location of the *inc* cistron(s) which code for incompatibility is according to Willetts⁷. The location of the origin of DNA transfer is represented as an arrowhead and is according to Davidson *et al.*¹¹. The location of the *tra* cistrons are according to the map order defined genetically³, the correlation of genetic results between different sets of mutants by Willetts and Achtman², and the correlation of genetic results with physical results by Davidson *et al.*¹¹. The *tra* cistrons listed are known to map between the dotted lines on the basis of the length of genetically characterised deletions. *traS* lies between *traG* and *traD*⁷ but its exact location is not yet known. The location of *traL* is according to the results presented by Willetts⁶ correlated with the results presented here. The locations of the promoter (p) and operator (o) are according to the results presented here. The arrow under the *tra* cistrons depicts the transcriptional direction of the *tra* operon as demonstrated here.

Table 1 Genetic locations of Mu-1 insertion mutants

Method	No. of mutants in												Total
	J	A	E	K	B	C	F	H	G	S	D	I	
1	0	0	0	0	0	0	3	5	0	0	10	1	19
2	0	3	2	0	7	2	9	7	2	0	0	0	32
3	1	6	0	0	0	0	0	0	0	0	0	0	7

For all three methods, Mu-1 lysates were spotted on bacterial cultures of (JCFLO)⁺ derivatives of strains JC3272 (methods 2 and 3) or JC5455 (method 1)²⁴. JCFLO is a *lacI*⁻ derivative of *Flac* (F42)²⁴. After 4–6 h at 37 °C for lysogenisation, subcultures were inoculated in nutrient broth with 0.01% SDS (methods 2 and 3) or without SDS (method 1). Overnight growth at 37 °C was conducted to allow segregation and expression. For method 1 dilutions were plated and the resulting colonies screened for Tra⁻ mutants by replica-plate crosses²⁴ against a *thr::Mu-1* F⁻ recipient culture. For methods 2 and 3, the overnight cultures were diluted into nutrient broth without SDS, grown to exponential phase and mated with a Mu-1 resistant derivative of Hfr KL98. His⁺ (Str^R) recombinants were selected on minimal medium plates containing SDS. For method 2, the His⁺ recombinants were screened for Tra⁻ and Sfx⁻ mutants by replica-plate crosses²⁷ against *thr::Mu-1* derivatives of an F⁻ recipient and an (F8)⁺ donor strain, respectively. For method 3, replica-plate crosses were first used to transfer R100-1 from a Mu-1 resistant (R100-1)⁺ donor culture to the His⁺ recombinants and these (R100-1) derivatives were then screened for M12-resistant clones. All the mutants listed were isolated from independent cultures and are of independent origin. A further 33 mutants isolated by method 2 are described in the text.

Sfx⁻ mutants. By incorporating 0.01% sodium dodecyl sulphate (SDS) in liquid and solid media, mating pair formation can be prevented, thus facilitating the isolation of Sfx⁻ mutants²⁰. The procedure used (ref. 20) consisted of including SDS in all growth media to prevent loss of Sfx⁻ mutants and included an enrichment for Sfx⁻ mutants by selecting recombinants after a mating between the mutagenised population and an Hfr donor. The recombinants were enriched approximately 100-fold for Sfx⁻ mutants compared with the (poor recipient) Sfx⁺ wild type.

The above information enabled us to design three mutant isolation procedures intended to yield (Mu-1)⁺ mutants which were, respectively, Tra⁻ Sfx⁺, Tra⁻ Sfx⁻ and *traJ*⁻. In the first procedure, we screened 39,000 (Mu-1)⁺ lysogens of an (*Flac*)⁺ strain for Tra⁻ mutants after an overnight growth step in the absence of SDS. As expected, a number of Sfx⁺ mutants (11/19) was isolated, in addition to eight Sfx⁻ mutants which escaped the natural selection against such mutants during growth of mixed populations. For the second procedure, SDS was present in all growth media to prevent loss of Sfx⁻ mutants and these mutants were then enriched by a mating with an Hfr donor culture followed by selection of recombinants. SDS was omitted during the mating. We screened 13,000 recombinants of (Mu-1)⁺ lysogens of an (*Flac*)⁺ strain and 65 Tra⁻ Sfx⁻ mutants were isolated. The first 32 analysed genetically by complementation tests seemed to represent an adequate sample of the *tra* cistrons except *traJ*, and the remaining mutants were tested only to ensure that none carried a *traJ*⁻ mutation. The complementation tests of the 65 mutants just described demonstrated that each mutant gave poor complementation for one or more clustered cistrons. We assigned a tentative genetic location for each Mu-1 insertion as being in or immediately to the left of the left-most cistron which was poorly complemented (Fig. 1). This assignment is demanded by the results of complementation tests with deletion mutants³ which demonstrated that any

polycistronic operons are transcribed from left to right. The genetic locations of the mutants are presented in Table 1. No *traJ*⁻ mutant was isolated by procedures 1 or 2 and the complementation results (discussed in detail below) did not enable any conclusion to be drawn about whether or not *traJ* was in the same operon.

The third procedure took advantage of the special properties of *traJ* and *traA*. As described above, *traJ*⁻ mutants lack the gene products of the other *tra* cistrons including *traA*^{12,21}. Willetts²¹ has shown that cells carrying either a *traJ*⁻ mutant or a *traA*⁻ mutant of F, plus the sex factor R100-1 (which has considerable DNA homology with F within the *tra* region²²) are relatively resistant to M12 male-specific bacteriophage, while cells carrying R100-1 and an F factor mutant in any other *tra* cistron are sensitive. Although the mechanism of this phenomenon is still not totally clear, we took advantage of it as a screening procedure for *traJ*⁻ mutants. We thus repeated the procedures used in the second method but in addition a strain carrying the R100-1 factor was mated with the selected recombinants; (R100-1)⁺ progeny were screened for M12-resistant clones by replica plating methods. The corresponding non-R100-1 containing colonies on the master plates were purified and analysed. Seven mutants were isolated out of 200,000 recombinants of which six carried Mu-1 in *traA* and one carried Mu-1 in *traJ*.

All the mutants listed in Table 1 have been shown to carry Mu-1 on the F factor since after acridine orange curing²³ to remove the F factor, the ability to produce Mu-1 phage was concurrently lost. All 58 mutants in Table 1 were tested for their DNA transfer ability and their surface-exclusion ability by replica-plating methods and in 33 out of 58 cases, chosen as representative of the various *tra* cistrons, by quantitative measurements as well. The qualitative and quantitative results (Table 2) were essentially the same as those described for deletion mutants^{3,7} which contained sequentially longer deletions

Table 2 Properties of Mu-1 insertion mutants

Mu location	No. of mutants	TE*	SEI†	F ₁	F ₂	QB ³
<i>traI</i>	1	≤ 3 × 10 ⁻⁷	67	S	S	S
<i>traD</i>	3	≤ 1 × 10 ⁻⁵	≥ 200	S	R	S
<i>traD</i>	1	≤ 1 × 10 ⁻⁵	46	S	R	S
All other cistrons	27	≤ 1 × 10 ⁻⁶	1–3	R	R	R
<i>traH</i>	1	≤ 1 × 10 ⁻⁶	13	R	R	R

S, Sensitive; R, resistant.

*The transfer efficiency²⁴ (TE) is defined as the number of (*Flac*)⁺ exconjugants derived from the F⁻ parent which are formed in a mating between the mutant strain used as donor and a suitable F⁻ recipient. The value is normalised for the number of mutant cells added to the mating mixture.

†The surface exclusion index²⁴ (SEI) is obtained by dividing the number of recombinant colonies measured in a mating between an Hfr and an F⁻ culture by the number measured in a parallel mating between the Hfr and a test culture. A value of 0.5 to 1.0 for the TE and 100 to 200 for SEI are typical of a wild type (*Flac*)⁺ culture.

These results were obtained with complementation tests performed 144 at a time in Microtiter plates as before^{1,23} but with an improved normalisation method. The values representing poor complementation are underlined. Each test consists of two successive crosses in which first an amber-suppressible *tra* mutant was introduced from a Su^+ host into the Su^- (Mu-1)⁺ insertion mutant strains. The degree of complementation was measured in the second cross by measuring the transfer efficiency of this population to an F^- (Mu-1)⁺ recipient after first killing the Su^+ primary donor with T6 phage. Normalisation was possible by always including an *Flac tra^+ lacZ^-* mutant (amber *lac* mutation) as donor and a different *Flac tra^+ lacZ^-* mutant (temperature-sensitive *lac* mutation) as recipient in every set of crosses. When F transfer by complementation due to the *tra^+ lacZ^-* donor was tested, a $Su^- F^-$ host was used in the second cross so that transfer of only the complemented mutant was measured. When F transfer by complementation due to the *tra^+ lacZ^-* recipient was tested, a $Su^+ F^-$ host was used in the second cross (transfer of the *Flac lac^-* mutant itself is not seen since these cells are *Lac^-* at the incubation temperature of 37 °C). The use of these two *Flac lacZ^-* mutants enabled us first to normalise the various donor cultures against the *lacZ^-* recipient mutant where all are complemented, and second to normalise the various recipient cultures against the *lacZ^-* donor mutant which also complements all of them. These two normalisations remove any effects due to different recipient ability of the individual recipient cultures and to different donor ability of the individual donor cultures.

running from *traL* leftwards. All mutants mapping to the right of *traS* were Sfx^+ and Tra^- and made F pili. All mutants mapping to the left of *traS* were Sfx^- and Tra^- and male specific phage resistant. The mutants tested only by replica-plate methods yielded qualitatively identical results.

The possibility existed that Mu-1 was not integrated at the site of the *tra* mutation, but elsewhere on *Flac* in the various mutants. This possibility was tested for a representative group of the mutants by using transduction with P1 phage to introduce *tra^+* DNA from a wild-type *Flac* element, followed by a mating to select Tra^+ recombinants. The mating was performed at 33 °C with a lysogenic F^- recipient with a temperature-sensitive Mu-1_{ts62} prophage integrated in *thr*. Since the recipient is immune to Mu-1 phage at 33 °C, both *Flac* elements either carrying Mu-1 or not carrying Mu-1 will establish themselves after transfer, and zygotic induction will not occur. At 42 °C the immunity due to the chromosomal Mu-1 prophage disappears and the cells die due to temperature induction unless the *Flac* element carries a Mu-1 prophage. Thus we could determine how often Tra^+ recombinants that were still lysogenic for Mu-1 were formed. Fifty colonies were tested from each cross: in all cases the Tra^+ colonies did not contain Mu-1 on *Flac* and the corresponding mutants must therefore carry Mu-1 inserted at the site of the *tra* mutation.

Operon structure

Table 3 presents results of complementation tests, using the conjugational complementation method¹ with the same

representative mutants mentioned above. Each Mu-1 insertion is polar on the neighbouring cistrons to the right regardless of where Mu-1 is inserted, except for Mu-1 in *traJ*. Furthermore, most of the Mu-1 insertions showed clear polarity on all the cistrons to the right of the insertion, although in many cases the polarity was not absolute. The Mu-1 insertion in *traJ* showed no polarity effects. The polarity pattern indicates first, that the direction of transcription for *traA* to *traD* is from left to right (Fig. 1) in agreement with results from deletion mutants³. Second, the 11 cistrons *traA* to *traD* must lie in one operon. These results also agree with the properties of three polar *traK* mutants, one polar *traC*, and one polar *traH* mutant which showed polarity through to *traS*^{1,2,20}. In addition 15 other amber, ochre, UGA or frameshift mutations, lying between *traB* and *traS* have also been shown to exert some polarity on *traS* (unpublished observations of M. A. and N. Willetts).

The results in Table 3 also indicate some residual complementation in tests between Mu-1 insertion mutants and mutations located distally in the *tra* operon. Such complementation was not observed in tests between deletion mutants and the same point mutations³ and therefore this low level of complementation demonstrates that the Mu-1 insertions have not deleted the cistrons being tested. This residual complementation is discussed further below.

The cistrons *traL*, *traK* and *traI* are not testable by the method described above for technical reasons, and so these three cistrons were tested by the P1 transductional method² (Table 4). These results taken together with those of

Table 4 P1 transductional complementation analysis with reference mutants

Location of Mu-1	P1kc lysate from	% complementation with recipient mutation		
		<i>traL311</i>	<i>traK105</i>	<i>traI65</i>
<i>traJ</i>	MPFL10	35	10	16
<i>traA</i>	MPFL6	0.05	< 0.01	< 0.1
<i>traE</i>	MPFL5	86	< 0.01	< 0.1
<i>traB</i>	MPFL4	101	9	< 0.1
<i>traC</i>	MPFL11	112	96	< 0.1
<i>traF</i>	JCFL171	78	73	< 0.1
<i>traH</i>	JCFL161	167	6	< 0.1
<i>traG</i>	JCFL184	118	11	< 0.1
<i>traD</i>	MPFL2	199	257	< 0.1
<i>traI</i>	JCFL146	179	272	0.3

These tests were performed as described previously² except that P1kc was used instead of P1virA. Negative values are underlined. P1kc lysates grown on the (Mu-1)⁺ insertion mutants were used to transduce strains carrying an *Flac* mutant carrying either *traL311*, *traK105* or *traI65* mutations. Complementation of the resulting abortive transductants was then assayed by crosses with an F^- strain. All results were normalised to a value of 100% for a P1kc lysate grown on a wild type *Flac* element after previous normalisation for the few colonies obtained due to leakiness in control transductions with a P1kc lysate grown on an F^- strain.

Willetts define the map location of *traL* as being between *traA* and *traE*. Furthermore Mu-1 insertions between *traA* and *traD* exert polarity on *traL*, *traK* and *traI* only when they lie to the left of that cistron. The Mu-1 insertion in *traI* did not manifest any polar effects.

The conclusion that the *tra* operon extends to *traI* was reinforced by the results of a third method. Willetts²¹ has shown that *traI*⁻ and *traJ*⁻ point mutants are not complemented for DNA transfer by the related sex factor R100-1 although point mutants in all other *tra* cistrons are complemented. Tests of (R100-1)⁺ derivatives of point mutants and of Mu-1 insertions in *traJ*, *traA*, *traC*, *traD* and *traI* confirmed these conclusions for the point mutants but indicated that all the Mu-1 insertions were not complemented by R100-1. These results are those expected if Mu-1 insertions between *traA* and *traD* exert polarity on *traI*. Thus all the cistrons between *traA* and *traI*, inclusive, form one operon transcribed in the direction *traA* to *traI* and henceforth referred to as the *tra* operon. *TraJ* must be part of a second operon, whose transcriptional direction is unknown.

The residual complementation shown in Table 3 in crosses where polarity was present might be due to reinitiation within the *tra* operon, to Mu-1 insertions not being absolutely polar, or to the formation of *Tra*⁺ recombinants. The complementation seen is, however, at the limit of resolution of the method used for Table 3. The nature of the complementation was therefore investigated by a much

traH, *traG*, *traS*, *traD*, and *traI* lie in one polycistronic operon. These conclusions are strengthened by the properties of other polar mutants available which were isolated after nitrosoguanidine or ethyl methanesulphonate treatment^{1,2,20,24}. Figure 1 shows that this operon has a maximal length of 93–62=31 kb. This stretch, however, includes *traJ* which is in a second operon. Since *traI* is to the right of 90 kb and *traE* is to the left of 68 kb, a minimal estimate is provided by assuming 0.3 kb for *traI* and 1 kb for *p o traA traL traE* yielding 90–68+1.3=23 kb. Thus the operon is 23–31 kb (or 15×10⁶–20×10⁶ daltons) long. If the mRNA is synthesised as one continuous piece it would be approximately 7×10⁶–10×10⁶ daltons long and take 7–10 min to transcribe at the rate of 55 nucleotide base pairs per second²⁵.

traA through to *traH* code for the synthesis of F pili and *traA* has been found to code for the F pilus subunit (personal communication from C. C. Brinton, Jr). *traG*, *traD* and *traI* mutants synthesise F pili and even form mating pairs with F⁻ cells²⁴. No DNA transfer ensues, however, from these mating pairs and *traG*, *traD* and *traI* probably code for enzymes involved directly in DNA transfer. *traS* codes for surface exclusion and expression of *traS* prevents DNA transfer from *Tra*⁺ cells²⁰. Thus, although these cistrons code for different functions, they are all DNA transfer-related.

Surface exclusion has a strong evolutionary advantage since the *Tra*⁺ *Sfx*⁻ mutants that we have isolated are

Tube complementation tests¹ were performed using transient heterozygote cells carrying both *Fhis tra*⁻ and *Flac tra*::Mu-1 mutants. The transfer efficiency per heterozygote RecA⁺ or RecA⁻ cell is shown. The Rec⁺ hosts were the same strains used in Table 2 whereas the Rec⁻ hosts were closely related *recA58* derivatives.

more sensitive tube complementation method¹. For these tests the *Flac* Mu-1 insertion mutants were transferred to a RecA⁻ host. Furthermore, *Fhis tra*⁻ mutants were isolated after recombination between *Fhis* (F57¹) and the appropriate *Flac tra* mutants containing point mutations. The genetic character of both the new *Fhis tra* mutants and the transferred *Flac* Mu-1 insertion mutants were confirmed with the same methods as used for Table 3.

Fhis/Flac heterozygote cells can be assayed by the formation of Lac⁻/Lac⁺ sector colonies and thus it is possible to estimate directly the complementation efficiencies per heterozygote cell. The results of such tests are presented in Table 5. Other tests between *Flac* mutants with Mu-1 in *traF*, *traH*, *traB* and *traD* and mutants carrying *Fhis traA1* or *traD83* were also performed with comparable results (data not shown). The conclusion from all these tests is that some residual complementation is in fact seen in both RecA⁺ and RecA⁻ hosts in crosses where polarity should result in no complementation. Complementation was accompanied by recombination in the Rec⁺ host but no *Tra*⁺ recombinants were formed in any of the crosses in the RecA⁻ host (data not shown). Thus either Mu-1 insertions are not absolutely polar in this system or there is some low level reinitiation within the *tra* operon.

Implications

The data presented here on Mu-1 insertion mutants demonstrate that *traA*, *traI*, *traF*, *traK*, *traB*, *traC*, *traE*

unstable in normal growth conditions²⁰. This instability would result in the selection of *Tra*⁺ *Sfx*⁺ mutants from a primaevial *Tra*⁺ *Sfx*⁻ population in nature in conditions where transfer was possible. It has possibly also been this selection pressure which resulted in the incorporation of *traS* into the *tra* operon since surface exclusion is thus expressed whenever the potential for DNA transfer is expressed.

The elucidation of the *tra* operon structure also simplifies any models to explain the mechanism of action of the *traI* gene product. *traI* is a positive control gene^{1,2} and *traI*⁻ mutants lack the gene products of all the other *tra* cistrons¹². A simple model to explain these relationships is that the *traI* gene product is necessary for transcription of the *tra* operon. In the case of the F factor, *traI* is always expressed as is the *tra* operon. Most R factors are repressed²⁶ and in at least the case of R100 the mechanism seems to be by the prevention of the synthesis of the *traI* gene product^{12,27,28}. Thus R factors can provide economy and repress the formation of sex pili, DNA transfer enzymes and surface exclusion by indirectly repressing the *tra* operon in a cascade fashion. There are always a few non-repressed cells in a repressed population which can transfer R factor DNA immediately on contact with R⁻ cells. After transfer to the R⁻ cells the *traI* gene product is synthesised before the repressor²⁸, the *tra* operon is turned on and the new R⁺ cell can itself transfer R factor DNA to any other R⁻ cells. Thus, essentially, the R factor DNA

transfer occurs when a repressed R^+ population is mixed with an R^- population. As soon as all the cells have received the R factor, surface exclusion prevents further DNA transfer. In the absence of DNA transfer no new *traJ* gene product is synthesised due to the repressor and dilution of the *traJ* gene product eventually leads to a newly repressed population in which neither *traJ* nor the *tra* operon are expressed.

We thank T. Trautner, D. Kamp, R. Kahmann and A. Ahmad for useful discussions; P. van der Putte for Mu-1 and Mu-1_{ct862} phages, and S. Schwuchow for technical assistance.

letters to nature

Discovery of powerful transient X-ray source A0620–00 with Ariel V Sky Survey Experiment

ON August 3 a faint new X-ray source was discovered (at 15 Ariel counts s^{-1}) near the boundary of the Monoceros and Orion constellations and 6° from the galactic plane, during routine monitoring of the Milky Way with the Ariel V Sky Survey Experiment (SSE). During the following week, the source—designated A0620–00—increased

rapidly in intensity to become the brightest in the sky (at 2–18 keV). The X-ray light curve from continued observation with the SSE to August 16 is shown in Fig. 1. The ordinate is in Ariel counts s^{-1} and for comparison, the corresponding count rates for the Crab Nebula and Sco X-1 are 400 s^{-1} and 3,200 s^{-1} , respectively. The precursor peak on August 6 is real and is qualitatively similar to the feature seen¹ in the rise to maximum intensity of the earlier Ariel transient A1524–62. Subsequent observations of A0620–00 with the Ariel V experiments pointing along the spin axis of the spacecraft have shown the intensity to have remained very high at least until August 27.

Figure 2 shows a copy of the Palomar Observatory Sky Survey chart marked up with the initial SSE X-ray source position, an improved Ariel V location² and the optical counterpart³ discussed in the following letter⁴. Figure 3 compares an expanded blue print of the region from the Palomar survey and a post-transient blue photograph taken with the UK Schmidt telescope at Siding Spring. In spite of the considerably reduced exposure of the new plate, limited by sky brightness—since A0620–00 is at present visible only near twilight—the considerable brightening of the optical star ($\Delta M_B \sim 8$) is readily apparent. Detection of a short lived radio source coincident with the optical star is reported in a later letter⁵.

Most current theories of optical novae^{6,7,8} invoke unstable mass transfer in a close binary system in which the accreting star is probably a white dwarf. The transient nature of A0620–00 indicates that this may have a similar origin, but the high X-ray luminosity strongly suggests a qualitative difference from optical novae (none of which have been detected by, admittedly incomplete, X-ray surveys), probably in that for an 'X-ray nova' to occur the accreting object has to be a neutron star or black hole. In the present case it is of particular importance to determine the distance and thus the X-ray luminosity of A0620–00. If, as seems likely, the source reached a maximum intensity from August 12 corresponding to an accretion rate at the Eddington limit, then the measured X-ray flux above 1 keV ($\sim 650 \text{ keV cm}^{-2} \text{ s}^{-1}$) corresponds to a limiting X-ray luminosity ($1.3 \times 10^{38} \text{ erg s}^{-1}$) for a secondary of mass M_\odot at a distance of 1 kpc. A preliminary analysis of high dispersion spectra of the optical star (Dr T. Gull, personal communication), reported to show marked interstellar absorption features⁹, gives a minimum distance of 600 pc,

Fig. 1 The X-ray light curve of A0620–00 obtained with the SSE at 2–18 keV. The error bars are $\pm 1 \sigma$ statistical errors at the lower intensity end (see inset); towards the peak the major error arises from uncertainties of 0.1° in the spacecraft attitude.

Fig. 3 A comparison of the optical counterpart on the blue POSS photograph with a post-transient blue plate taken with the UK Schmidt telescope at Siding Spring (courtesy: Science Research Council, UKSTU)

whereas the discovery of an earlier optical outburst of A0620-00 in 1917 (ref. 10) has been interpreted in terms of a recurrent nova which, if of typical luminosity for a 60-yr period nova, would indicate a distance of 5,700 pc. If confirmed, a distance of this order would imply that the accreting component of A0620-00 is a massive black hole.

Finally, a search for periodic variation in the X-ray intensity of A0620-00 has shown no modulation ($>3\%$) over time scales of 200 s – 2 d.

The X-ray spectrum of A0620-00

A REMARKABLE change in the X-ray spectrum of the transient source A0620-00 (ref. 1) was observed by the Ariel V Sky Survey Experiment (SSE) during the rise to maximum brightness. The SSE detector being used has an effective area (behind its field collimator) of 290 cm² and covers the energy band 2–18 keV in 8 channels. The channel boundaries are marked in Fig. 1, which shows sample pulse height spectra taken as the source intensified. These raw data have not been corrected for the detector efficiency and at this stage include no input spectral assumptions. Two points emerge clearly: when first detected the X-ray spectrum of A0620-00 was hard and remained so as the overall intensity rose to the precursor peak and, secondly, the subsequent rise to maximum intensity was entirely due to a strong enhancement of X rays below 10 keV, giving a marked softening in the overall spectrum. In fact, the observed flux above 10 keV actually fell during this period.

To quantify these changes, the pulse height spectra have been compared with a range of input spectra defined by a spectral parameter (power law index or thermal spectrum kT) and cutoff energy, folded with the known detector response and normalised to the observed data. Table 1 summarises the best fits obtained for spectra at different times in the X-ray light curve, χ^2 indicating the quality of a particular fit. The notable softening of the spectrum as the source brightens can now be quantified as, for example, an increase in the power law index from 0.6–0.7 in the precursor peak to ~ 4.0 near maximum brightness. The corresponding thermal spectral fits show a corresponding decrease in kT from ~ 30 to 1.5 keV. The rather large values of χ^2 indicate that the spectrum is generally too complex to be fully described by a single parameter fit, most spectra having excess observed counts in the upper one or two energy channels.

Figure 2 shows the input power law spectrum which matches the data quite well from 2 to 15 keV for modified Julian date (MJD) 40.5, just after maximum brightness. Also shown are two higher energy points obtained over the period MJD 44.5–47.5 with the Imperial College scintillation counter on Ariel V (A. Engel, personal communication), during which time the intensity remained steady. Again, the highest energy SSE spectral point shows some excess counts, and the presence of a harder component above 15 keV is supported by the Imperial College data. The best fit power law of Fig. 2 includes

Table 1 Parameters of best-fit X-ray spectra

Modified Julian date(42,600+)	Power law input spectrum				Thermal input spectrum			
	$I(E) = AE^{-\alpha} \exp(-E_a/E)^{8/3} (\text{keV cm}^{-2} \text{s}^{-1} \text{keV}^{-1})$				$I(E) = \frac{A \exp(-E/kT)}{E^{0.3}} \exp(-E_a/E)^{8/3} (\text{keV cm}^{-2} \text{s}^{-1} \text{keV}^{-1})$			
	$\alpha(\pm 2\sigma)$	$E_a \pm 2\sigma$ (or 2σ upper limit)	A	χ^2_{min}	$kT(\text{keV})$	$E_a(\text{keV})$	A	χ^2_{min}
28.8–29.4	0.65 ± 0.15	< 1.0	5.5 ± 0.6	56	20^{+15}_{-5}	< 0.7	3.7 ± 0.4	83
30.1–30.5	0.6 ± 0.15	< 1.3	13.2 ± 2.8	27	29^{+40}_{-15}	< 1.0	9.9 ± 1.6	38
31.0–31.4								
(a) $E < 6.2 \text{ keV}$	1.4 ± 0.1	< 1.0	71	12	8.7	< 0.5	22	280
(b) $E > 6.2 \text{ keV}$	0.2 ± 3.0							
32.72	3.1 ± 0.2	< 1.2	$(1.83 \pm 0.47)10^3$	31	1.36 ± 0.1	< 0.75	950 ± 110	152
33.14	3.7 ± 0.25	1.85 ± 0.25	$(7.1 \pm 2.3)10^3$	19	1.35 ± 0.07	< 0.8	$(1.18 \pm 0.17)10^3$	78
34.20	3.75 ± 0.15	1.9 ± 0.15	$(11.9 \pm 3.3)10^3$	27	1.37 ± 0.07	< 0.6	$(1.4 \pm 0.2)10^3$	100
35.10	4.0 ± 0.2	2.15 ± 0.15	$(8.8 \pm 2.6)10^3$	25	1.36 ± 0.05	< 0.75	$(6.1 \pm 0.5)10^3$	74
40.5	4.15 ± 0.2	2.6 ± 0.2	$(20 \pm 7)10^3$	22	1.52 ± 0.1	$1.1^{+0.4}_{-1.1}$	$(1.05 \pm 0.3)10^3$	26

a finite low energy cutoff of $E_a = 2.6 \text{ keV}$ and examination of all the existing spectra suggests a significant low energy attenuation becoming evident as the source intensifies.

The spectral evolution reported above provides interesting insight into the nature of A0620–00. Considering a binary model with unstable mass transfer, as referred to briefly in the preceding letter, the hard ‘precursor’ emission may be interpreted as arising from the hottest regions of an accretion disk lying close to the compact star. Then, as further mass is accreted, the disk grows rapidly, giving a corresponding increase in the overall X-ray intensity. Since the outer parts of this enlarged disk will be cooler the resulting X-ray spectrum will soften. Furthermore, the reduction in flux above 10 keV as the source increases towards maximum brightness may well be due to the hot inner regions of the disk being partially

Fig. 1 Pulse height spectra of A0620–00 obtained during the rise to maximum brightness. The time of each spectrum is marked in MJD and error bars are $\pm 1\sigma$ for each spectral channel.

Fig. 2 The best-fit power law spectrum for the SSE data of MJD 40.5 (spectral index 4.1, low energy cutoff 2.6 keV) together with higher energy points from the Imperial College crystal spectrometer (experiment F on Ariel V) taken during MJD 44.5–47.5. Error bars are $\pm 1\sigma$.

obscured by the mass of outlying gas. A detailed analysis of the light curve and spectral evolution of A0620–00 presented here may be anticipated to yield important details on the accretion flow and disk formation in such close binary systems.

Observations of A0620-00 at 962 and 151 MHz

FOLLOWING the discovery by the X-ray astronomy group at Leicester University of a large increase in the X-ray flux of A0620-00, observations at 962 MHz and 151 MHz have been made at Jodrell Bank. During the period August 16-29, observations were made at 962 MHz with the MK II-MK III long baseline radio-link interferometer. This instrument has a spacing of 23.7 km giving a lobe size of $\sim 3''$ at this frequency. The radio-link is phase compensated so that integrations can be made for several hours.

Fig. 1 Flux density of A0620-00 at 962 MHz with a resolution of $3''$

On August 16 and 18, the instrument was used to survey an area 0.5° by 0.5° centred on the position of the X-ray source¹. For a source at declination 0° the synthesised beam after integrating from hour angle 1.5 – 3.5 h is $5''$ in right ascension and $30'$ in declination. In the area surveyed only one source, at the extreme edge of the field, was significantly above the noise level. On August 19 the position of an optically variable object, possibly associated with the X-ray source, was communicated to us². The right ascension of this object and the observed radio source agreed to within $6''$ making an association likely. Further observations were therefore restricted to a smaller area of sky surrounding the position of the radio source and optical object. Thus a wider bandwidth could be used, giving an increased sensitivity and enabling the position to be measured with greater accuracy. With the 4-MHz bandwidth the r.m.s. noise on an amplitude measurement after a 2-h integration was 6 mJy. The position measured on August 18 was: $\alpha = 06$ h 20 min 11.4 ± 0.27 s; $\delta = -0^\circ 17 \pm 7'$ (1950.0). Subsequently, more accurate measurements of the X-ray source position confirmed the radio identification^{3,4}. No significant variation of fringe amplitude with hour angle was detected during the observations, thus indicating that the angular size of the radio source was less than $3''$. Measurements of the flux density of the radio source were continued until August 29 and showed a decreasing intensity with time as shown in Fig. 1.

During August 12-15 observations were also made at 962 MHz using the MK II radio telescope. Total power measurements indicated that the flux density of the source was less than 5 Jy. On August 17, 20, 23 and 24 observations were made using the MK IA-Defford radio-link interferometer at 151 MHz. This instrument has a baseline of 127 km which gives a lobe size of $3''$ at this frequency. No radio emission was observed down to a sensitivity limit of 250 mJy. At this frequency, however, interstellar scattering may increase the apparent angular

size of a source near the galactic plane, as in the case of Cyg X-3 (ref. 5), and this could explain why no source was observed in the present observations at 151 MHz.

If the decrease of flux density shown in Fig. 1 is expressed as an exponential decay, the time for the flux density to fall by a factor of $1/e$ is 5.2 d. The data may also be fitted to a power law of the form $t^{-\beta \pm 1}$ on the assumption that the outburst originated on August 3.0 UT. On the simple van der Laan model⁶ of uniform expansion of an optically thin cloud of relativistic electrons, this would correspond to a radio spectral index, α , of -0.25 ± 0.25 where α is defined by $S = S_0 \nu^\alpha$.

The optical counterpart of A0620-00 before its eruption

AN accurate position of the optical counterpart of A0620-00 discovered by Boley and Wolfson¹ has made possible the identification of the image of the star on the Palomar Observatory Sky Survey (POSS) charts.

The position was measured on two 10-min exposures on Eastman Kodak Ila0 plates taken on the 13-inch astrographic telescope at Herstmonceux on August 27-28 and 28-29, 1975 relative to standard positions of AGK3 stars, using a Zeiss x - y measuring engine. It was reduced using the methods described by Murray, Tucker and Clements². The mean position of the Boley-Wolfson star which appears at $B \sim 12.2$ on both plates is: $\alpha = 06$ h 20 min 11.176 ± 0.021 s; $\delta = -00^\circ 19' 10.80 \pm 0.32''$ (1950.0), where r.m.s. errors are quoted. There is a substantial contribution to these errors from the uncertainty of the system defined by the AGK3 stars and from the possible effects of refraction if the identification has a different colour from the AGK3 stars. The right ascension lies about 3 s.d. ($1.20 \pm 0.35''$) from that of the radio object measured at the Mullard Radio Astronomy Observatory³. The position is, however, within the X-ray error boxes measured by the Leicester⁴ and Birmingham-Mullard Space Science Laboratory⁵ experiments on Ariel V and by the Massachusetts Institute of Technology experiment⁶ on SAS-3.

The positions of a number of stars on the POSS charts (from originals taken on November 18-19 1955) were also determined with respect to the same AGK3 standards from measurements made with a Faul Coradi Coradigraph x - y machine. Similar reductions showed that one star, identified in Fig. 1, lies at: $\alpha = 06$ h 20 min 11.202 ± 0.023 s; $\delta = -00^\circ 19' 10.45 \pm 0.35''$ (1950.0).

In comparing these two positions the errors of the positional system defined by the AGK3 stars cancel and so the difference in position has smaller errors than the appropriate combination of the errors in the positions. The differences between the measurements obtained on the POSS and the 13-inch plates are: $\Delta\alpha = +0.39 \pm 0.38''$ and $\Delta\delta = +0.35 \pm 0.38''$. Since the positions agree very well and the next nearest object on the POSS is $\sim 15''$ away, the star identified in Fig. 1 is very likely to be the optical counterpart before its eruption.

Eye estimates on the POSS give magnitudes in 1955 for the counterpart of $B \sim 20.5$, $B - R \sim 3.6$ where the errors are likely

Fig. 1 Chart identifying the image of the optical counterpart of A0620-00, before its eruption, on the POSS red chart (copyright: National Geographic Magazine-Palomar Observatory Sky Survey).

to be ~ 0.5 mag. From these magnitudes the star is unlikely to be a giant since it would then lie at a distance of at least 15 kpc which would place it far from the plane and pose difficulties in reconciling the observed X-ray flux with the Eddington limit⁴ if the X-ray source has a mass similar to that of the Sun. If it is a K dwarf the estimated colour would demand some obscuration, presumably circumstellar perhaps arising from earlier outbursts⁷, and a distance of the order of 500 pc. Such obscuration would be of interest in view of reports⁸ of interstellar lines. In addition, the magnitude expected⁴ from extrapolating the X-ray spectrum near maximum to the optical region as an optically thin bremsstrahlung source, is $B \sim 8$, which may also indicate the presence of interstellar absorption, although it could also represent self-absorption in the hot gas emitting the X-rays.

If the optical counterpart before eruption is a red dwarf star, this is consistent with a model for the X-ray source resembling current explanations of dwarf novae (see for example ref. 9), but with a black hole or neutron star replacing the white dwarf as the body accreting material spilt from the Roche lobe of the red star.

We thank Professor K. Pounds for discussions and early communication of unpublished results. M. J. W. is supported by a SRC studentship.

Galactic superhaloes, globular clusters and high latitude X-ray sources

I show here that the observational features of unidentified, high latitude, X-ray sources¹ are consistent with the suggestion that they are a population of remote, optically undetectable, globular clusters. The principal objection to the hypothesis that the high latitude sources are members of any galactic population is their isotropy in galactic longitude. But if it is assumed that the most distant unidentified high latitude source radiates at 10^{38} erg s⁻¹ (a typical value for a bright globular cluster X-ray source^{2,3}) and that it is the faintest unidentified high latitude source, visible at 1-2 Uhuru counts s⁻¹, its distance would be ~ 200 kpc. Then, extrapolating to the brightest unidentified source at 7 counts s⁻¹, we get a lower bound on the minimum distance to any objects of about 80 kpc, and the volume toward the galactic centre, between $-90^\circ < l'' < 90^\circ$ in the 'shell' from 80 to 200 kpc, differs negligibly from the volume toward the anticentre, at $90^\circ < l'' < 270^\circ$. Although a specific radiation model is used in this case, the luminosities do not affect the basic result.

It is widely believed that the globular cluster population of the Galaxy is essentially completely observable⁴; however, that may not be the case. Table 1 shows concentration class

Table 1 Average absolute photographic magnitude of different classes of globular clusters*

Class	M_{pg}	Class	M_{pg}
I	-7.9	VII	-7.5
II	-7.8	VIII	-7.2
III	-7.8	IX	-6.7
IV	-7.8	X	-6.2
V	-7.7	XI	-5.7
VI	-7.6	XII	-5.2

*Data from ref. 5.

against average absolute photographic magnitude for 91 clusters⁵, and it can be seen that as the cluster gets more diffuse (higher number class), the integrated absolute magnitude falls. Indeed, out to an apparent value of $m_{pg} = 15$, all clusters are known only to concentration class X or tighter⁴. And, in fact, 10 of the 12 'new' globular clusters detected in the Palomar Sky Survey plates are in class XI or XII (ref. 6). These new clusters are difficult to detect because of three characteristics: they are intrinsically fainter than the others, they are diffuse (and thus more difficult to discriminate from the general field), and they are far away.

Pal 3 and Pal 4 have been examined photometrically⁷. Those particular clusters are about 100 kpc away, and it is possible that because of their faint absolute magnitude, such objects may populate space in great numbers and remain undetected⁷. The average B magnitude of the 25 brightest stars in these clusters is $\sim 20^4$; even Pal 12, 33 kpc away, has an average B magnitude of 17.5 for its 25 brightest stars. These faint magnitudes, and the diffuse nature of the clusters make it likely that the NGC and IC catalogues would not include other similar objects⁴. Since the limiting red magnitudes of the Palomar plates are ~ 20 ,—assuming that the red giant stars have $M_v = 0.0$ with the total integrated cluster magnitude $M_v = -6$ (ref. 7; see also Table 1)—then all clusters fainter than $m_v \approx 14$ will probably be undetectable. Pal 3 and Pal 4 have m_v values of 14.2 and 14.4, respectively⁷.

The difficulty of detecting distant faint clusters is demonstrated by Fig. 1. Clearly, the visible globular clusters are on the edge of detectability.

The distribution of the number density of the globular clusters against the distance from the galactic centre^{4,8} describes well the spatial density of the nearer clusters, but that is not so at large distances. Figure 2 shows the number of globular clusters in 10 kpc shells, against the distance from the galactic centre, for all clusters whose distances are known¹.

Further, 6 globular clusters have been observed at > 80 kpc and none at all have been observed between 50 and 80 kpc. To explain these observations, I propose that the density distribution of globular clusters changes, becoming roughly proportional to the volume element at a point in space 50–80 kpc from the galactic centre. With such a model a preponderance of clusters could be expected at about the limit of detectability, since beyond that point the clusters would not be visible by definition, whereas at closer distances the volume surveyed and thus the number of objects observed would be smaller.

Approximately 150 unidentified, high latitude, X-ray sources have been observed down to ~ 1.5 Uhuru counts s^{-1} (after coverage corrections)¹. If it is assumed that X-ray sources occur in these remote, diffuse clusters in the same ratio—4/119—as in the nearer clusters², about 4,500 class XI or XII globular clusters would have to be present between roughly 80 kpc, where the first 'distant' clusters are observed, and the limit of 200 kpc. Assuming a constant space density gives: $\rho = 1.3 \times 10^{-4}$ clusters kpc^{-3} . That is almost exactly equal to the space density of globular clusters between 20 and 30 kpc; and 4,500 clusters with an initial mass of $\sim 10^5 M_{\odot}$ are still much less massive than the Galaxy.

The possibility that high velocity stars form 'moving groups', belonging to the halo population, has been discussed^{9,10}, and it has been suggested that these groups may share an equality of motion because they are remnants of globular clusters. It has been estimated that the number of parent globular clusters is of the order of 10^3 (ref. 10).

Fig. 1 Region around Pal 4, a remote globular cluster. Inset, 200'' plate of the same object taken by Burbidge and Sandage⁷ (covering the area of sky boxed in the main figure). Scale bar, 6'; inset scale bar, 60''.

Fig. 2 Number of globular clusters in 10 kpc shells against distance from the galactic centre. ♦, Predicted values based on $\rho \propto r^{-2.7}$ normalised to the value observed between 0 and 10 kpc; χ^2 per degree of freedom is 0.8 out to 40 kpc, and 3.3 out to 80 kpc. For a $\rho \propto r^{-2.9}$, χ^2 is 1.4 and 2.4 out to 40 kpc and 80 kpc, respectively.

The observational implications are clear: searches should be made for variability, and the positional accuracy of the high latitude X-ray sources should be improved. Also, deep sky plates in the red should be made. Further distance estimates to clusters for which information does not already exist would help in understanding the true density distribution function. If, indeed, the unidentified high latitude sources are stellar objects in a superhalo population of diffuse globular clusters, then the log N –log S curve¹ should flatten beyond the true edge of the halo.

I thank Garrett Jernigan, James Buff, William Liller, and George Clark for discussions.

Gas well pressure fluctuations and earthquakes

AN important part of earthquake prediction studies is the search for various precursors. It is likely that one precursor may not enable us to predict an earthquake correctly, but a collection of these may remove the uncertainties. It is also desirable to find data that are recorded routinely, in enough detail, such that they can be conveniently used by seismologists.

In so far as the permeability (due to pores and/or joints) and the pressure gradient in a reservoir may be influenced by stress, production and well-head pressure data from oil and gas wells may prove to be useful. There has been an attempt to search for precursory phenomenon in monthly oil well production data¹. On the other hand, many examples exist already of changes of levels and flow rates in water wells before and after earthquakes^{2,3}; it is reasonable to expect that oil and gas wells would behave in much the same way.

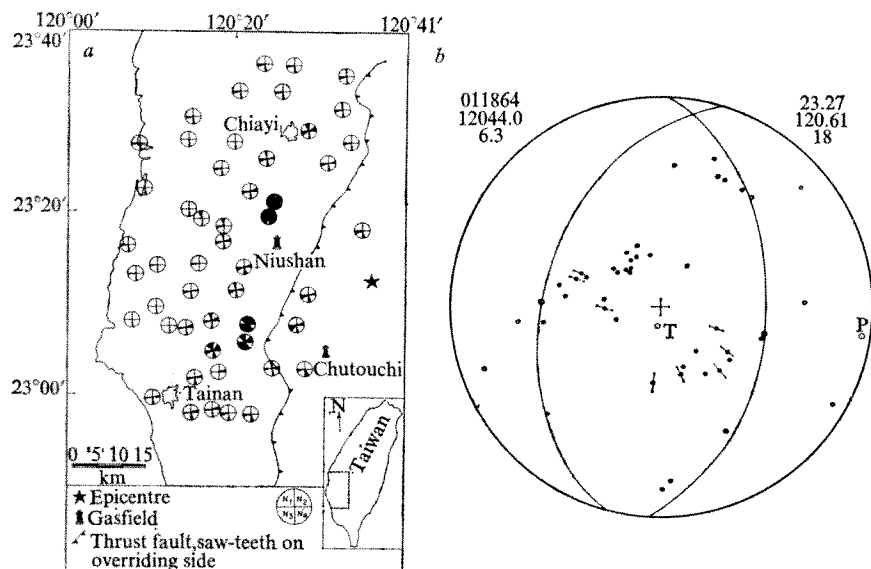

Fig. 1 *a*, The location of the earthquake epicentre, the causative fault and the Niushan and Chutouchi gas fields. The damage figures are indicative of the extent of the source region to the west of the fault, where the towns (indicated by circles) are of approximately equal size in terms of population and number of structures. To the east of the fault, in the mountainous area urbanisation is much less dense. The numbers N_1, N_2, \dots are normalised to the maxima. N_1 , no. of dead; N_2 , no. of wounded; N_3 , no. of houses collapsed; N_4 , no. of houses damaged. *b*, The lower hemisphere equal area projection of the focal mechanism of the January 18, 1964 earthquake. T, tension axis; P, compression axis.

Here we report a case of pressure or production changes in two gas fields in Taiwan before a 6.75 magnitude (Pasadena M_s) earthquake.

Figure 1*a* shows the location of the Niushan and Chutouchi gas fields, the epicentre and the extent of damage. This region is very active seismically and since the mid-1600s, when historical records became available in this area, many destructive earthquakes have occurred here. The earthquake of January 18, 1964 (origin time 1204:40.0 GMT; depth 17 km (W. H. K. Lee and J. P. Yang, unpublished)) is apparently related to an east dipping thrust fault mapped by surface as well as subsurface geological data. The fault plane solution is shown in Fig. 1*b*. From the magnitude of the event and the damage pattern (Fig. 1*a*), the fault length associated with this earthquake is of the order of 15–35 km (ref. 4); the Niushan field is within 8 km and Chutouchi field 12 km of the surface trace of the causative fault and are therefore within the source region of the earthquake.

Niushan gas field produces from upper Pliocene units that are composed of alternating beds of sandy shale, silty sandstone, shale and fine to medium grained sandstone. Chutouchi field produces from lower Miocene fine compact sandstone and badly sorted silty sandstone. In both fields the porosity is low and the gas was produced from jointed and fractured rocks⁵.

Both gas fields were in operation between 1957 and 1970. Of the more than ten wells in Niushan gas field, only three were not pumped. Ideally both well-head pressure and production rate data for such wells are useful, since both are related to the change in permeability and/or pressure gradient in the reservoir resulting from tectonic stress. The production data in Niushan field are not usable, however; apparently the total production of the field, including pumped wells, is correct, but the individual readings were rough estimates.

Because of the presence of water in the well and the bubbling of gas, the pressure varies between daily maxima and minima; the pressure is recorded continuously, but only the maxima and minima were entered in the production records which were used in this work. In Fig. 2, the daily maxima and minima since January 1, 1964 are plotted for the three wells. There are rather clear increases (15–60%) in pressure for all three wells for both daily highs and lows, starting from January 8. Careful examination of records covering several years shows that such rapid change did not appear; the pressure readings have short term variations of $\pm 0.1 \text{ kg cm}^{-2}$ superposed on a very slowly decreasing trend for several years before the earthquake. After the earthquake, there was a noticeable short term fluctuation in one of the wells, but not in the other. It should be noted that a break in the piping system occurred during the earthquake resulting in open flow of the wells and an ensuing drop in well

pressure. The pressure returned to the level existing before January 9 after the pipes were repaired on January 20, although one of the wells (R-10) was permanently damaged during the earthquake.

Fig. 2 The well-head pressure variation before and after the January 18, 1964 earthquake (arrow) at Niushan gas field. *a*, Well R-10, depth 988.6 m; *b*, well R-7, depth 717 m; *c*, well R-23, depth 385 m.

Fig. 3 Gas production rate data at Chutouchi gas field, before and after the January 18, 1964 earthquake. Depth of wells: EB-10, 1,440 m; EC-14, 1,324 m; EC-15, 1,850 m; EC-16, 1,490 m.

The increase in pressure before the January 18 earthquake is apparently a precursor to the earthquake.

At the Chutouchi gas field, on the hanging wall side of the thrust (Fig. 1), the pressure and production rate showed only slight changes during the period of January 1–18. We then looked at the production rate data for all three wells from 1958 and found that superposed on a general long term slow decrease, there is a noticeably more rapid drop beginning after March 1963 (Fig. 3); after the earthquake the trend became steady again. (The drop in total production after the earthquake was caused by the disruption of one well during the earthquake.)

The difference in well pressure behaviour at these two fields before the earthquake may indicate the different behaviour of reservoirs under stress on two sides of the causative fault; Niushan gas field is on the foot wall side and Chutouchi field on the hanging wall side. The exact mechanism of this behaviour can be postulated only after the stress field around the fault and the joint system are known in detail.

As demonstrated by Myachkin and Zubkov⁶, earthquake precursors can be classified into short term and long term. The Niushan pressure change can be classified as a short term precursor, although the time interval between the commencement of this precursory change and the occurrence of the earthquake is an order of magnitude longer than most of the results of Myachkin and Zubkov (see figures in ref. 6). On the other hand, if the Chutouchi data are a true precursor, then they are closer to being a long term precursor.

Because the pressure and production data are continuously monitored by the oil companies, they may be a worthwhile source of evidence of the existence and usefulness of this precursor in other gas and oil fields.

This research was supported by grants from the NSF. I thank the Chinese Petroleum Company personnel in Taiwan for help in securing the data.

Gravitational drive on oceanic plates caused by thermal contraction

PROPOSED mechanisms for the motion of lithospheric plates over the Earth's surface range from the self-drive of plates by gravitational sliding^{1,2}, through passive response to mantle-wide convection³, to point drive by upwelling hotspots in the mantle⁴. All of these models depend on the distribution of effective viscosity within the mantle. Investigations⁵ have established the strong likelihood that a weak layer (10^{20} poise) exists immediately below the lithosphere, and long spatial-wavelength loadings associated with changes in the Earth's rotation⁶, together with the larger scale components of glacial loading⁵, demand that this asthenosphere be quite thin (100 km) and bounded by material from the lower mantle with a viscosity of two to four orders of magnitude higher.

As an analogy, this situation can be visualised as a layer of ice, over a layer of water, over a layer of honey 30 times as deep. Thus it can be seen that the plates (the ice in this analogy) would not be well coupled to motions in the lower mantle (the honey), and, indeed, that the highly viscous lower layer would be unlikely to flow faster than the surface layer. Several observations support this concept. Morgan⁷ has constructed plate histories that require very little relative motion between hotspots, and there is significant coincidence between the hotspot frame of reference and a frame of reference derived by minimising the motion of plate boundaries⁸.

The boundary-layer theory of plate accretion has received strong support from the discovery of the square-root law of

implied by this relationship, and the material must be assigned a constant volume expansion coefficient, γ , for the calculation of $\rho(z)$. Then

$$\rho = \rho_A \gamma (T_1 - T) = \rho_A \gamma T_1 \operatorname{erfc} [z/2\sqrt{(\kappa t)}]$$

giving h and, therefore, α (see ref. 9):

$$h = [1/(\rho_A - \rho_w)] \int_0^\infty \rho dz = (1/\sqrt{\pi}) [\rho_A \gamma T_1 2\sqrt{(\kappa t)} / (\rho_A - \rho_w)]$$

$$\alpha = \frac{dh}{dx} = \frac{1}{s} \frac{dh}{dt} = \frac{1}{\sqrt{\pi}} \frac{\rho_A \gamma T_1}{s(\rho_A - \rho_w)} \sqrt{(\kappa/t)}$$

where s was the spreading velocity of the lithosphere when it was formed, and $\beta - \alpha$ may be found from the slope of the locus, $l = 2y\sqrt{(\kappa t)}$ (constant y):

$$\beta - \alpha = \frac{dl}{dx} = \frac{1}{s} \frac{dl}{dt} = \frac{y}{s} \sqrt{(\kappa/t)}$$

thus, equation (4) becomes:

$$\begin{aligned} \frac{dF}{dx} - \tau = \frac{g\rho_A \gamma T_1 \kappa}{s} \left[\frac{1}{\sqrt{\pi}} + \left(1 + \frac{\rho_A \gamma T_1}{y\sqrt{\pi}(\rho_A - \rho_w)} \right) \times \right. \\ \left. \times \left(\frac{1}{\sqrt{\pi}} (1 - e^{-y^2}) + y \operatorname{erfc} y \right) - 2 \left(\frac{1}{\sqrt{\pi}} (1 - \frac{1}{2} e^{-y^2}) - \frac{1}{4y} \operatorname{erfc} y + \frac{1}{2} y \operatorname{erfc} y \right) \right] \end{aligned}$$

where it should be noted that the integrals of the error function differ from the standard forms because of integration from 0 to y instead of from y to ∞ . Finally, this simplifies to:

$$\begin{aligned} \frac{dF}{dx} - \tau = \frac{g\rho_A \gamma T_1 \kappa}{s} \left[\operatorname{erfc} y + \frac{2\rho_A \gamma T_1}{\sqrt{\pi}(\rho_A - \rho_w)} \times \right. \\ \left. \times \left(\frac{1}{\sqrt{\pi}} (1 - e^{-y^2}) + y \operatorname{erfc} y \right) \right] \quad (5) \end{aligned}$$

the second term of which can be neglected for reasonable values of y , γ and T_1 . For example, ridge topography has been⁹ well fitted by using $\rho_A = 3.3 \text{ g cm}^{-3}$; $\gamma = 4 \times 10^{-5} \text{ }^\circ\text{C}^{-1}$; $\kappa = 8 \times 10^{-3} \text{ cm}^2 \text{ s}^{-1}$; $T_1 = 1,120 \text{ }^\circ\text{C}$ (Pacific Ocean). The parameter γT_1 is, therefore, 0.045, and the choice of y is not critical as is shown in Table 1.

Presuming that asthenosphere material becomes essentially rigid after a relatively small drop in temperature, the final result can be written simply as

$$dF/dx - \tau \approx g\rho_A \gamma T_1 \kappa / s = 7.2 \text{ bar} \quad (s = 5 \text{ cm yr}^{-1}) \quad (6)$$

the most startling feature of which is that it is independent of the age of the lithosphere. For comparison of figures, the drag on lithosphere moving at 10 cm yr^{-1} over 100 km of asthenosphere of 10^{20} poise, is 3 bar. In the absence of such drag, the lateral compressive stress developed over 5,000 km of plate 100 km thick at its end is $50 \times 7.2 = 360 \text{ bar}$.

The conclusions this analysis points to are both simple and important. The overall magnitude of the driving force is similar to that derived by some authors^{10,12} but not to that derived by Jacoby¹. There is no source for the high compressive stresses invoked by Watts and Talwani¹³ to explain the topographical bulge and high gravity on the seaward side of many trenches. The thermal contraction force is independent of the age of the lithosphere and is only dependent on the velocity at which it was originally spread. It is not an edge

Table 1 Variation of parameters with y

y	0	1	2	3
$T/T_1 = \operatorname{erfc} y$	0	0.843	0.995	0.99998
$h \propto \int_0^y \operatorname{erfc} y$	0	0.524	0.563	0.564

force associated only with active mid-oceanic ridge crests, as assumed by Forsyth and Uyeda¹⁴. This removes one of the two arguments advanced by McKenzie¹² against plate drive by ridges: that is, small plates should not necessarily move faster than large plates. Another argument¹² is that the mechanical work produced by the ridges is insufficient to account for the elastic energy released in earthquakes. This is easily refuted by the observation that the majority of energetic earthquakes are associated with subduction zones. More mechanical work is generated by sinking lithosphere than by gravitational sliding from ridges, but this work is not necessarily available to drive the plates. Analysis based on the correlation of plate movement with boundary composition¹⁴ shows that the subduction zones contain both the largest driving force and the greatest resistance to flow. Although only edge drive by ridges is permitted, the conclusion arises inexorably from the fact that all fast moving plates are bounded by trenches. Unfortunately, this may merely reflect the inability of any fast-moving plate to override another without generating a huge resistance.

The thermal contraction drive is ample to push plates over any asthenosphere that complies reasonably with the known constraints, and the presence of subduction zones may exercise indirect control over plate motions by providing the only available low resistance against the forward end for fast moving plates. A more serious objection to drive by thermal contraction is the fact that in large mountain ranges the lateral stresses in the lithosphere would have to be about three times greater than can be provided by ridges^{2,10}. The answer to this objection is, in part, similar to that to the problem of earthquake energy: the largest mountain ranges are associated with sinking slabs, present or past. The excess hydrostatic pressure at shallow depth under an isostatically compensated mountain range can be partially balanced by a pressure deficit at intermediate depth if the region is underlain by anomalously dense mantle. An extra oceanic slab, slung flat beneath a mountain range, can provide a regional 'suction' equal to the drive provided by the ridge, and that is increased further in the extra mountain 'root' region needed to compensate for the slab. Long tilted slabs can create even larger 'suction' forces. The other class of substantial mountain ranges, associated with continental rift zones, are probably uplifted by thermal expansion and magma buoyancy¹⁰. Since they are rifting, compensatory horizontal compression is not required.

Coated optical guides for spectrophotometry of chemical reactions

A NEED exists for a method of detecting small amounts of chemicals in air and other gases, and in solutions, simply, and with a high degree of sensitivity. We have developed a new technique based on the concept of using waveguide phenomena in combination with chemical reactions. This technique is applicable to a wide variety of chemical reactions, including biochemical systems, provided that they cause a change in light transmittance by virtue of a change in colour, refractive index, or light scattering. Both real-time and cumulative measurements are possible.

The theory underlying light guide phenomena is well understood and has been treated extensively by Kapany^{1,2}. We felt it should be possible to alter the transmission properties of an optical guide using a chemical reaction on the surface of the guide, since a change in refractive index at the interface with the rod surface alters the critical angle. Initially, reactants were applied directly to a rod which functioned as a lightguide. Changes in light intensity were observed qualitatively as a

Fig. 1 Mechanism models.

reaction was carried out on the surface. But problems in coating adhesion were encountered using this technique. Consequently, a solution of water-soluble polymer and reactants was prepared, which was then used to coat a 1.0×20 mm quartz rod. Thus, the polymer acted as a bonding agent and matrix, and also offered protection to the reactants incorporated in the coating.

The lightguide coating combination can be chosen to provide a coating with a refractive index that is either higher or lower than the rod (guide) and which can be either a water or non-water based polymer, depending upon its compatibility with the desired chemical reactants. A lower refractive index is normally used in optical guide applications and would result in the mechanism illustrated (Fig. 1a).

Using the higher refractive index coating, the mechanism shown in Fig. 1b would be operative. Although either approach can be used, the mode shown in Fig. 1a would result in lower sensitivity since the evanescent wave interactions occur only in the region of the rod-coating interface. In either of the mechanisms shown in Fig. 1b, the radiation is transmitted

through the entire coating and so allows solid state spectrophotometric measurements *in situ*.

To measure the light transmittance, an instrument was designed and constructed to provide quantitative analytical measurements. This 'gradient light analytical detector' (GLAD) will accommodate glass rods of 0.9–1.3 mm in diameter, and either 10 or 20 mm long (Fig. 2).

A detailed view of the GLAD optical system is also shown in Fig. 2, with rod dimensions exaggerated to illustrate the basic instrumental operation. The substage condenser converts the collimated beam into a strongly converging hollow cone of light. The hemispherical lens and circular aperture couple the light into the rod. After multiple reflections within the rod, the light emerges at the upper face and is scattered by a diffuser, part of the light going into the silicon photodiode detector. The photodiode is operated in the photovoltaic mode, the operational amplifier acting as a current sink to minimise the voltage across the diode. The amplifier output is a low impedance voltage, proportional to the input current over a range of 10^{-11} – 10^{-3} A.

To demonstrate the concept, we used the technique for the determination of microgram quantities of sodium cyanide in a cyanide-picric acid system. A solution was prepared to contain 1% by weight of polyvinyl alcohol and 0.1% by weight of sodium picric acid, which is known to respond selectively to $(CN)^-$ (ref. 3). This solution was then used to coat the surface of the rods uniformly when the ends were protected.

The light transmission of the dry, coated lightguides was measured before reaction. Known amounts of cyanide ion, in the form of sodium cyanide, were applied to the outer surface of the guides using a 5 μ l Eppendorf pipette, the rods were dried, and the transmission was measured again. The percentage transmission, based on the initial reading before exposure, was then plotted as a function of the $(CN)^-$ concentration (Fig. 3).

The reaction between the cyanide ion and the picric acid changes the refractive index and absorption coefficient of the coating. The resulting change in light transmission through the guide is proportional to the concentration of the cyanide species. The multiple internal reflections enhances the sensitivity, in that a small change in the optical characteristics of the coating

Fig. 2 Block diagram of the gradient light analytical detector (GLAD). 1, A tungsten filament lamp light source; 2, a condenser system to produce nearly collimated light; 3, a filter for wavelength selection; 4, an annular aperture to block axial light rays; 5, a condenser to produce a hollow cone of light rays; 6, coupling hemispheres and apertures to couple large angle rays into the rod; 7, a rod mount to position rods accurately with respect to the aperture while presenting a minimum of surface contact; 8, a silicon photodiode detector; 9, an operational amplifier operating as a 'current-voltage' converter; 10, a three-digit digital voltmeter for relative transmittance readout. a, Detector; b, rod; c, hemisphere; d, condensers; e, annular aperture.

causes a large change in the light transmitted through the system. A green filter provides the best sensitivity, as can be anticipated because of the reddish-brown colour of the reaction product; further, Beer's law is obeyed over the expected range of concentration.

Implications of drought for vertebrate fossil assemblages

THE profound effects of drought on modern ecosystems is widely appreciated. However, little attention has been paid to the palaeontological and geological consequences of drought; the few works¹ which discuss drought in these terms are general. I wish to describe a sequence of events that may occur during a drought and the taphonomic implications of these events.

It is well known that factors such as habitat preference of the animals in question^{2,3}, the degree of disruption of bones by

carnivores⁴, and the environmental setting⁵ influence the likelihood of preservation of thanatocoenoses. My preliminary observations of the Ethiopian drought during 1973 indicate that these factors and many others are affected considerably by drought. I suggest that assemblages of vertebrates that die during a drought may have a disproportionate probability of being represented in the fossil record and that such assemblages can be recognised by the characteristic alterations of an ecosystem by drought.

Tannehill⁶ offers a useful definition of drought as a period of deficient rainfall which is seriously injurious to local vegetation. He avoids defining drought in terms of the amount of rainfall, since what is normal rainfall in one area may be deficient in another. I describe three hypothetical phases of progressive severity of drought. Although the effects of a normal dry season may be the same as some of those described for these phases, it is the complex of effects that indicates an abnormal period of dryness—drought—as opposed to a normal dry season.

In phase I, mild drought, rainfall is less than usual. New vegetation withers quickly or fails to grow; large migratory herbivores move in search of better pastures and more water; seasonal waterholes and streams dry up; mortality is elevated above normal attritional levels, especially among younger individuals.

In phase II, severe drought, rainfall continues to be deficient. Permanent rivers and lakes are shrinking; caliche forms in the alkaline soil, evaporites precipitate and cracks develop in the beds of dried-up rivers and waterholes. Animals respond to the drought according to the frequency with which they need to drink water; thus highly mobile animals with moderate water needs may migrate out of the area. Those animals that need to drink at least once a day congregate along the remaining waterways regardless of their normal habitat preference. All edible vegetation within a critical distance of water is soon eaten, so only those animals that rarely drink water can travel far enough from water to find forage. Many animals die of starvation near major water sources. I observed numerous carcasses within 50 m of the Awash River in Ethiopia; thus the presence of a river or lake near a fossil assemblage in no way indicates the absence of drought. Carnivores may migrate into the area because of the easy availability of food. Observations of hyenas in the Awash suggest that even carnivores which habitually consume bones alter their habits during a drought and eat soft tissues instead; thus skeletons are rarely disturbed by the carnivores during this phase.

In phase III, extreme drought, normal rainfall is still absent. Large lakes and rivers may dry up, leaving huge numbers of dead fish, amphibians and other water-dwelling species. The few herbivores crowd around shrinking pools of water and die struggling to drink. Local extinction of plants and animals is common; extinction may occur on the species level as well. All but the most drought-resistant plants have died. The soil moisture and organic content are low; loose sand may be blown into dunes. If phase III continues long enough, the environment may be permanently altered into desert or semi-desert; in this case, the situation is no longer one of drought. The plants and animals which originally inhabited the area do not return and colonisation by organisms adapted to desert conditions occurs.

For several reasons, a large runoff is likely when rain recurs following phase II or III. The land surface is denuded of vegetation that normally traps and holds water. Caliche impedes the passage of rainwater into the soil, further increasing runoff. Both intermittent and permanent rivers may fill and overflow, transporting and depositing large quantities of sediment. Skeletons lying in or near river or lakebeds are covered rapidly by these sediments; fossilisation may begin.

So far, the few drought assemblages that have been recognised fall into phase III (ref. 7), probably because the effects of this phase are more easily recognisable than the more subtle effects of phase I or II. Phase I assemblages are difficult to distinguish from assemblages resulting from other catastrophes. Phase II

droughts, however, alter the ecosystem sufficiently to be identified. Since failure to recognise a phase II assemblage may seriously distort a palaeoecological reconstruction, it is important that phase II assemblages be distinguished. The following criteria may be used to identify phase II assemblages except those criteria specified as characterising phase III assemblages. No single criterion should be considered as diagnostic in itself, nor will every phase II assemblage exhibit all of these criteria.

The palaeontological criteria are as follows. (1) Since many animals die of starvation rather than thirst, they are buried close to major water sources. (2) The age distribution of individuals killed by drought is indicative of catastrophic mortality¹⁻³. Many young individuals die in phase I; those dying in phase II are likely to be in their prime. (3) Many skeletons are preserved partially or fully articulated because carnivores have not disturbed the bones. Because the palaeo-environment lacks moisture, soft tissues of carcasses are dried and help to keep joints intact⁹. (4) Animals of disparate habitat preference are found in association. Most species are highly dependent on water. (5) In phase III, aquatic or semi-aquatic animals die concentrated in small areas. (6) In phase III, animals such as crocodiles and lungfish die during aestivation. The geological criteria are as follows. (1) Fine-grained strata associated with the fossils show mud cracks. (2) Evaporites and caliche are commonly associated with the fossils but are uncommon in other strata of the deposit. (3) Overlying sediments indicate rapid deposition.

Further study of modern droughts will undoubtedly modify these criteria. Even in their present form, however, they may be useful in re-examining previously described fossil assemblages for which other causes of death have been proposed. On reconsideration, assemblages that include numerous herbivores found in death poses and located near major water sources—such as the *Leptomeryx* assemblages described by Clark and Guensberg¹⁰—may prove to be drought assemblages. Although it has been speculated before⁷ that drought may be related to the extinction of some species, these criteria will enable more certain identification to be made of such extinctions. Finally, if the geological criteria are correct, palaeontologists may be able to find new sites by surveying areas near water sources and characterised by caliche, evaporites and mud cracks.

I thank Kay Behrensmeyer, Diane Gifford, David E. Janes, M. E. Morbeck and John E. Sanders for helpful discussions, and John E. Sanders and Clifford Jolly for a critical reading of the manuscript.

Hypsilophodon and *Iguanodon* from the Lower Cretaceous of North America

WE describe here ornithopod dinosaur remains from the Lower Cretaceous of western North America, which can be referred to the European genera *Hypsilophodon* and *Iguanodon*. The occurrence of these remains indicate that a land connection existed between Europe and North America at the end of the Jurassic.

Though *Hypsilophodon* and *Iguanodon* are well known from Europe and northern Africa (Fig. 1a) no trace of either genus has yet been reported from North America and the only possible Neocomian ornithopod described from that continent is from the Lakota Sandstone of South Dakota and is referred to *Camptosaurus*¹, a genus well known from the older Morrison Formation (Upper Jurassic). *Camptosaurus*¹ is very different from both *Hypsilophodon*² and *Iguanodon*³. No material of *Iguanodon* is identifiable in the extensive collections from the Morrison Formation of central North America and all the hypsilophodontid material is referable to two genera⁴, *Laosaurus* and *Dryosaurus*. An extensive dinosaur fauna is known from the Cloverly Formation of Montana and Wyoming⁵ but this is younger (Aptian–Albian) than the Wealden, and the iguanodontid *Tenontosaurus*⁶, the only Cloverly ornithopod described,

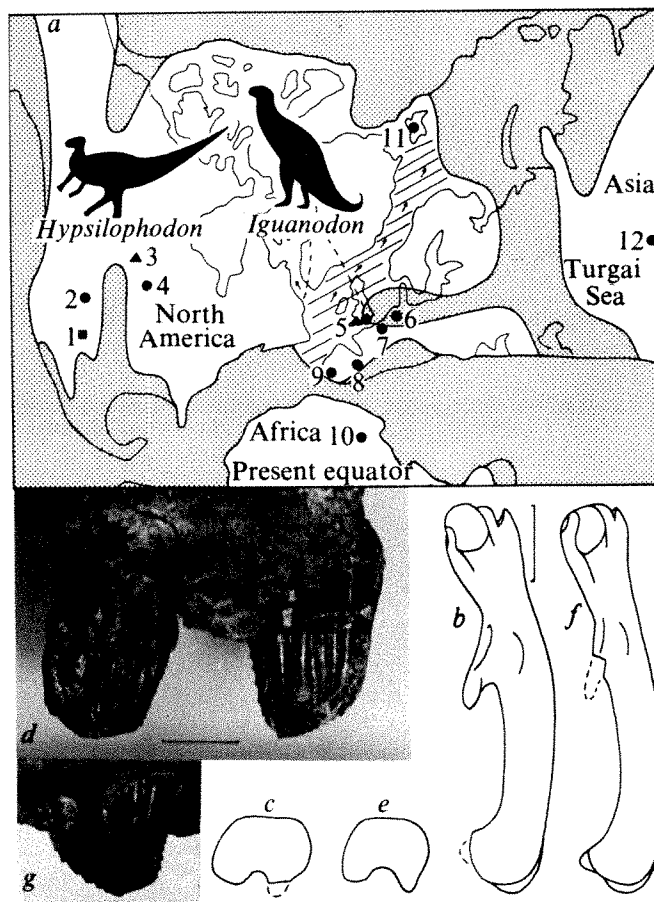

Fig. 1 a, Localities and distribution of land in part of the Northern Hemisphere during the early Cretaceous, after Cox¹⁷, — reconstructed coast lines; —, present coast lines; - - -, northern extent of North Atlantic, after Dietz and Holden²²; →→→, circulation currents, after Berggren and Hollister²¹; cross hatching, epicontinental sea, after Hallam²⁰; ▲, *Hypsilophodon* localities; ●, *Iguanodon* localities; ■, *Tenontosaurus* locality; 1, southern Arizona; 2, south-eastern Utah; 3, western South Dakota; 4, eastern Nebraska; 5, southern England; 6, Belgium; 7, France; 8, Spain; 9, Portugal; 10, Tunisia; 11, Spitzbergen; 12, eastern Gobi Desert (shifted slightly left). b and c, left femur ($\times 0.2$) of *Hypsilophodon* sp. (American Museum of Natural History No. 2585), collected in Lakota Sandstone about 38 m above the Morrison Formation 4.8 km north of Piedmont, South Dakota; b, medial view; c, distal end; d, lateral view of posterior part of right maxilla ($\times 1.0$) of *Iguanodon* sp. (Brigham Young University Earth Sciences Museum No. 2000), collected 1.2 km east of Dalton Well, Grand County, Utah; e and f, left femur ($\times 0.5$) of *Hypsilophodon foxii*, Wealden of Isle of Wight; e, distal end; f, medial view; g, lateral view of posterior tooth of left maxilla⁹ ($\times 1.0$) of *Iguanodon mantelli* (British Museum (Natural History) No. R754), from Wealden (Tilgate Forest) of Cuckfield, Sussex. Scale lines represent 5 cm (b, c, e, and f) or 1 cm (d and g); although the North American *Hypsilophodon* femur is much larger than the European specimen figured here, it falls within the size range of the genus⁴.

is only distantly related to *Iguanodon*. Consequently, the specimens described here (Fig. 1b, c and d) represent the first material of the characteristically European genera *Hypsilophodon* and *Iguanodon* to be recognised from North America.

The left femur (Fig. 1b and c), from the Lakota Sandstone of South Dakota, is very similar to the femora of *Hypsilophodon foxii*² (Fig. 1e and f). The other hypsilophodontid femora from North America differ from these in several respects. In *Hypsilophodon* itself there is a shallow cleft separating the proximal trochanters (Fig. 1b and f) whereas in *Laosaurus* (= *Nanosaurus rex*)⁸ and *Dryosaurus* the cleft is deep; in *Parksosaurus* (Upper Cretaceous), on the other hand, the cleft is apparently absent⁷. The distal end of the femur of *Hypsilophodon* (Fig. 1c and e) has practically no anterior intercondylar groove; this groove is, however, well developed in *Dryosaurus*, where the posterolateral condyle is thin, as it is in *Parksosaurus*⁷.

The posterior part of the right maxilla (Fig. 1d) was collected from the Lower Cretaceous Cedar Mountain Formation⁸ of south-eastern Utah. The teeth are very similar to some of those from *Iguanodon*⁹ (Fig. 1g) from Britain, and the Utah specimen is, therefore, probably referable to *Iguanodon* (D. Norman, personal communication). The thickly enamelled lateral surface of the crown has a prominent keel (Fig. 1d), whereas in *Tenontosaurus* only dentary teeth bear such a keel⁵. The presence of a deep vertical depression on the anterior and posterior edges of the root and base of the crown also serves to distinguish these teeth from those of *Tenontosaurus*⁵ and *Camptosaurus*¹. The distal end of a right femur from the same area as the maxilla has a very deep anterior intercondylar groove, as in *Iguanodon*³, again, this is in marked contrast to the shallow groove present on femora of *Tenontosaurus*⁵ and *Camptosaurus*¹. The distal end of a femur from the Dakota Sandstone of Nebraska¹⁰ can also be referred to *Iguanodon* on account of a very deep anterior intercondylar groove. The distal ends of the femora of certain hadrosaurs¹¹ are also similar to those of *Iguanodon*³, but hadrosaurs are not known to occur so early, the oldest known specimen from North America being late Cretaceous in age (Santonian, Mississippi)¹², though older records come from the Cenomanian of England¹³ and the Aptian-Albian of Mongolia¹⁴.

The North Atlantic started to open during the early Jurassic¹⁵ with a second stage of expansion, corresponding to the Bermuda discontinuity, probably ending sometime during the late Jurassic or early Cretaceous¹⁵. The presence of a 'transatlantic' land connection during the Middle Jurassic is clearly shown by the great similarity of the Upper Jurassic dinosaur faunas best known from the Morrison Formation of North America and the Tendaguru of Tanzania¹⁶⁻¹⁸. There are, however, no dinosaurian genera common to the Wealden Beds of Europe and either the Arundel Formation¹⁹ (Neocomian) of Maryland or the Cloverly Formation⁵. The specimens of *Hypsilophodon* and *Iguanodon* described here show that the presumed absence of these genera from North America reflect the lack of material from beds of appropriate age and/or ecology.

Reconstructions of the northern limit of the North Atlantic at about the time of the Jurassic-Cretaceous transition vary (Fig. 1a) but, taking into account epicontinental seas, the North Atlantic probably connected with the Arctic Ocean at that time^{20,21}. Epicontinental seas are, however, shallow and liable to retreat and advance locally, so they are not such an absolute barrier to terrestrial animals as are deep oceans. The presence of two characteristically European genera in North America indicates a northern land route between these two areas at about, or immediately before the Jurassic-Cretaceous transition. Future discoveries in the Neocomian of North America will probably increase the number of genera common to both areas. During the early Cretaceous the Mid-Continental Seaway of central

North America (Fig. 1a) had not extended far enough north to separate two distinct dinosaurian faunas in the northern hemisphere (Asiaamerica, Euramerica), as occurred in the Upper Cretaceous¹⁷.

The specimens discussed here will be fully described elsewhere²³.

Membrane augmentation in freezing tolerance of plant cells

THE question of the special physiology and biochemistry of growth and adaptation of plants to low temperature has been raised¹ with reference to the significance of the increased unsaturation of fatty acids observed in such plants. Interest in the phenomenon of increased unsaturation with exposure to low temperatures, first documented by Hilditch², has received impetus from reports^{3,4} that membranes and membrane lipids of plants sensitive to chilling change from a liquid-crystalline to a gel structure when exposed to low temperatures, whereas those from plants resistant to chilling undergo no such phase change. The implication was that the less unsaturated membrane lipids of cells or organelles from plants which are sensitive to chilling were less fluid at lower temperatures and consequently lost normal function at such temperatures. Reports of increased fatty acid unsaturation in phospholipids of plant tissues^{5,6} which are tolerant of chilling lend credence to these views. The apparently reasonable extrapolation from these findings that has been made⁷⁻¹¹, and that was inferred by Moore¹, is that the resistance of plants to injury from actual freezing may also be derived from changes in unsaturation and fluidity of membrane lipids. This theory warrants closer examination. The two stresses of chilling and freezing are quite different; chilling resistance is an adaptation to low temperatures above freezing and principally involves the interaction between metabolic function and structure, whereas freezing resistance is tolerance to the dehydrative stresses of crystallisation of ice, and seems to be largely structural in nature^{12,13}. It is reasonable to expect, therefore, that the underlying chemistry of resistance to chilling and freezing would be different. Our findings indicate that this is the case.

Two conclusions can be drawn from our results (Table 1). First, in the transition of the living bark cells from the summer unhardy (LD₅₀ -10 °C) to the winter hardy (LD₅₀ > -196 °C)

Table 1 Fatty acid composition and PC:PE ratios of summer and winter living bark tissues of the black locust tree

Tissue	Phospholipid	Fatty acid composition (mol %)						Δ /mol*	PC:PE†
		16:0	18:0	18:1	18:2	18:3			
Summer (LD ₅₀ -10 °C)	Total	21.4	1.7	5.8	62.8	8.3		1.6	1.5
	PE	23.7	1.5	4.8	64.1	5.9		1.5	
	PC	15.7	2.2	6.7	63.1	12.2		1.7	
Winter (LD ₅₀ > -196 °C)	Total	19.8	0.4	2.3	69.7	7.7		1.6	1.6
	PE	23.2	0.4	1.8	69.1	5.5		1.6	
	PC	12.8	0.5	2.2	74.5	9.9		1.8	

Phospholipids extraction, separation and fatty acid determination were performed according to methods described previously¹¹.

* Δ /mol = $1.0 \times (\% \text{ monoene})/100 + 2.0 \times (\% \text{ diene})/100 + 3.0 \times (\% \text{ triene})/100$.

†By mol.

condition no significant change occurs in the fatty acid unsaturation of either of the two major phospholipids, phosphatidylcholine and phosphatidylethanolamine. These results extend our finding¹⁴ of a lack of change in unsaturation in both the total lipids and combined phospholipid fractions. Second, no significant shift occurs in the proportions of the two major phospholipid classes. These results agree with those of Yoshida and Sakai¹⁵ for the poplar tree. Changes in fluidity of membranes arising merely from increased unsaturation or from a shift in phospholipid classes cannot, therefore, be the factors responsible for the development of extreme freezing tolerance. In contrast to trees, herbaceous plants do undergo large increases in unsaturation during hardening^{9,10}, which must be a result of exposure to the low temperature regimes required for hardening since winter wheat cultivars of contrasting hardness exhibit the same degree of unsaturation¹⁶. It is also interesting that the relative unsaturation of tree cells in their hardest condition (LD₅₀ > -196 °C) is still less than that of cereals in their most tender state (LD₅₀ -2 °C).

So far the only change we have observed in the locust bark cells that is consistent with the development of extreme freezing tolerance is the augmentation of membranes. Table 2 demonstrates the quantitative augmentation of membrane components on a DNA or unit cell basis. The development of

Table 2 Augmentation of phospholipid and protein in insoluble homogenates of summer and winter black locust bark tissues.

Tissue	Temperature at		Phospholipid/DNA	Protein/DNA
	LD ₅₀			
Summer	-10 °C		4.7	14.0
Winter	> -196 °C		11.1	33.0

Insoluble homogenates were prepared as described in ref. 11. DNA was measured by estimation of adenine content after Schmidt-Thannhauser extraction and removal of RNA (J. S. and D. S., unpublished). LD₅₀ refers to the temperature at which 50% of the cells were killed. Values presented represented means of three replicates.

tolerance to freezing must, therefore, be associated directly with this increase in membranous material as we have also been able to produce, by starvation of these cells graded levels of resistance to freezing which correlate directly with graded concentrations of phospholipid¹³.

We suggest, therefore, that at least one of the mechanisms of resistance to freezing, and probably the major one in these trees, involves the augmentation of membranous material in their cells. The biochemical and biophysical mechanism by which membrane augmentation enables the cell to accommodate to the stresses of extreme freezing are being investigated further.

Superoxide dismutase in photosynthetic organisms provides an evolutionary hypothesis

Two years ago it seemed that a unifying hypothesis accounting for the distribution of superoxide dismutase (SOD) in different organisms had been achieved. Thus the enzyme was present only in aerobes and aerotolerant anaerobes, but absent from obligate anaerobes¹; eukaryotes contained primarily the cuprein (Cu-Zn) type of dismutase (cyanide-sensitive) whereas in prokaryotes the enzyme had either manganese or iron at the catalytic site (cyanide-insensitive); finally, the presence of a manganodisutase in the matrix space of mitochondria was interpreted² in terms of a polyphyletic origin for eukaryotes with independent evolution of SOD in the prokaryotes (Mn-SOD) and proto-eukaryotes (Cu-Zn SOD) before the postulated symbiotic event.

Several subsequent findings, however, have justified the cautionary nature of Fridovich's closing remarks to his hypothesis³. Lavelle *et al.*⁴ found only a single, manganese-containing SOD in the luminous fungus *Pleurotus olearius*; Lindmark and Muller⁵ reported cyanide-insensitive SOD activity in two aerotolerant protozoa; Puget and Michelson⁶ isolated a bacteriocuprein from *Photobacterium leiognathii*; Hewitt and Morris⁷ detected SOD in a wide range of obligate anaerobes, and, finally, Asada *et al.*⁸ noted the absence of cyanide-sensitivity in SOD from all algal phyla studied.

We have made an electrophoretic survey of the occurrence of SOD in photosynthetic organisms, both prokaryotic (bacteria and blue-green algae) and eukaryotic (red and green algae) (Fig. 1), and have confirmed the individual results of Hewitt and Morris and of Asada *et al.* All the organisms we studied contain cyanide-insensitive SOD activity and, in the case of the green alga *Codium*, a part of this activity has been localised in the chloroplast stroma. This contrasts with the situation in higher plants in which, so far, only the Cu-Zn enzyme has been found⁹⁻¹¹. We wish to suggest a new scheme for the evolution of photosynthetic organisms, relating the findings on SOD to the con-

ditions in which the initial symbiotic events are thought to have taken place.

The bacteriostatic effect of oxygen on *Chlorobium* and *Chromatium* may result because SOD cannot prevent the inactivation of certain enzymes vital to their metabolism (for example, Fe-S proteins). We must presume either (1) that SOD evolved independently in obligate anaerobes or (2) that SOD evolved before oxygenic photosynthesis as a result of the Urey effect, that is the production of oxygen by ultraviolet photolysis of water¹². There is no general agreement on the level of atmospheric oxygen which this would have produced¹³, but, if the enzymes from *Chlorobium* and *Chromatium* are as similar as the gels suggest, SOD must have antedated the divergence of these lines. It might be argued that some of the multiple bands of activity (especially those of *Chromatium*) do not represent genuine isozymes and are artefacts of electrofocusing or staining; however, the three activities of aerobically-grown *Rps. spheroides* extracts can be separated by ion exchange chromatography and give consistent single bands on gels.

The following scheme for the evolution of eukaryotic algae is constructed from the premise of the symbiotic origin of subcellular organelles, although the experimental findings are not incompatible with alternative hypotheses¹⁴. The sequence of events would have been initiated by the acquisition, by a photosynthetic bacterium, of a water-splitting enzyme system linked to the photosynthetic electron transport chain, resulting in an oxygenic photosynthesis similar to that of present-day algae and plants. We have proposed that this enzyme, which contains manganese, may originally have had a dual role, functioning also, in a soluble form, as a SOD so that oxygen-evolving and oxygen radical detoxification mechanisms could have appeared simultaneously¹⁵. An immediate effect of this photosynthetic oxygen evolution would have been to force an aerobic respiratory metabolism on primitive nitrate-reducing bacteria¹⁶. Certain lines of these primitive aerobes may have evolved

mechanisms for phagocytosis and entered into a symbiotic relationship with primitive blue-green algae, resulting in a cyanome-like organism^{17,18}. This would have been to the benefit of both partners, the blue-green alga would have an environment of lower oxygen tension and the host cell would have a stable source of oxygen independent of the algal colonies.

A second symbiotic association, between a cyanome and an aerobic prokaryote would, when stabilised, produce an organism similar to a present day red alga. de Duve¹⁹ and Hall²⁰ have discussed how it may have benefited an aerobic host cell to enter such a relationship with another aerobe. Indeed, Hall makes the point that, if the host cell already contained enzymes duplicating many of the functions of the endosymbiont, then the latter may have become dependent on the host enzymes, thus explaining the nuclear encoding of mitochondrial proteins such as cytochrome *c* and SOD²¹.

Two important points must be made about the environment in which these events took place. Hall¹⁶ considers that a photosynthetic population large enough to produce a net increase in atmospheric oxygen could not have been achieved without the evolution of the environmentally less demanding eukaryotic algae. Thus the evolution of quite advanced forms of eukaryotes can be envisaged as taking place within a restricted, oxygen-rich environment, although the atmosphere at large remained anaerobic. Weyl²² has proposed that the tropical thermocline could have fulfilled this role, vertical diffusion of oxygen between the density layers of the ocean being greatly restricted. Second, it has been pointed out that, in a reducing atmosphere, copper would have been largely trapped as insoluble cuprous sulphides²³. Following the scheme outlined above, soluble copper would not have become available until after the evolution of eukaryotic algae, so that the earliest eukaryotes would not have contained Cu-Zn SOD.

The acquisition of Cu-Zn SOD by certain lines of eukaryotic organisms must now be considered. Given that closely related organisms survive whether or not they contain Cu-Zn SOD (for example, higher plants and algae, *Neurospora* and *Pleurotus*, *Photobacterium leiognathii* and other *Photobacterium* spp.), it can be inferred that there are no important functional differences between the types of SOD. We suggest that, while the potentialities of copper as a catalyst in biological systems were being explored (for example, in cytochrome oxidase and plastocyanin) a copper protein evolved in one or two lines which was, fortuitously, an efficient SOD and that this enzyme coexisted with, or in some cases replaced, the existing dismutase. Such a possibility is perhaps not unlikely in view of the SOD activity exhibited by quite simple copper-peptide chelates²⁴ and by galactose oxidase²⁵. The reactions between cupreins copper and various catechols²⁶ may be an indication of the now relict function for which the cupreins were originally evolved. Bacteriocuprein can be regarded as such a phenomenon occurring independently in a prokaryote—the only case so far detected because prokaryotes in general make less use of copper in enzymes²⁷.

Fig. 1 Polyacrylamide gel isoelectric focusing of SOD from photosynthetic organisms. SOD in soluble extracts of the organisms was partially purified by fractionation with ammonium sulphate (50–90% saturation) followed by dialysis. These crude extracts were assayed with or without 1mM KCN by the photochemical method of Beauchamp and Fridovich²⁸ (because of the instability of cyanide this was prepared on the day of use); then 2–10 U of SOD were applied per gel which was run²⁹ and stained²⁸ as described. See also ref. 11. Ampholytes were obtained from LKB Ltd. From left to right, the organisms are: *a*, *Chlorobium thiosulphatophilum* (green bacterium); *b*, *Chromatium D* (purple, sulphur bacterium); *c*, *Rhodospseudomonas spheroides* (purple, non-sulphur bacterium) anaerobically grown; *d*, *Rps. spheroides*, aerobically grown; *e*, *Nostoc muscorum* (blue-green alga); *f*, *Anabaena cylindrica* (blue-green alga); *g*, *A. flos-aquae* (blue-green alga); *h*, *Spirulina platensis* (blue-green alga); *i*, *Porphyridium cruentum* (red alga); *j*, *Scenedesmus obliquus* (green alga); *k*, *Codium fragile* (coenocytic green alga) chloroplast stromal extract; *l*, *C. fragile*, cytoplasmic extract. In the light of present knowledge, it has been assumed that insensitivity to inhibition by cyanide is a valid criterion of the absence of the cuprein-type of SOD from crude extracts. Nevertheless, until several of these enzymes have been characterised, the possibility of the existence of a class of cyanide-insensitive, copper-containing dismutases should be borne in mind.

Cross-modal matching in the monkey after discrete temporal lobe lesions

ETTLINGER¹, reviewing the literature on cross-modal matching in primates, concluded that whereas man and chimpanzees seemed to be capable of such matching, the evidence concerning the monkey was ambiguous. Cowey and Weiskrantz², however, reported a method which resulted in a successful demonstration of a tactile-visual cross-modal match in normal rhesus monkeys. Their success seemed to result from the use of stimulus shapes made from powdered monkey diet, which the animal could eat. Such a training paradigm would be more natural—and therefore presumably easier—for the animal to master. In their experiment, monkeys were allowed to sample ten palatable and ten different unpalatable shapes (treated with quinine) in the dark; subsequently, the monkeys were given a choice between one palatable and one unpalatable shape, presented with the house light switched on. The monkeys chose the palatable shape significantly more often than the unpalatable, showing that a cross-modal match had occurred.

We have studied the effects of discrete temporal lobe lesions on cross-modal matching ability, using the Cowey and Weiskrantz method. Our subjects included three monkeys (two *Macaca mulatta* and one *Papio papio*) with foveal prestriate (FPS) lesions, two (one *M. mulatta* and one *P. papio*) with posterior inferotemporal (PIT) lesions and two monkeys (*M.*

mulatta) with anterior inferotemporal (AIT) lesions. These lesions are shown in Fig. 1. Each animal had an extensive history of testing on a visual delayed matching to sample task using colours, ellipses and curves as stimuli. These experiments showed that the FPS lesion produced no impairment, the PIT lesion resulted in animals with perceptual deficits and the AIT lesion produced an impairment that was significantly influenced by delay. In addition to these animals, two monkeys (*M. mulatta*) served as unoperated controls.

We used a standard Wisconsin general test apparatus (WGTA) and the transport cage which housed the monkeys was constructed so that shapes could not inadvertently become lodged within sight of the animal. Stimuli were prepared as follows: the positive shapes were made from Dixons powdered monkey diet (41-B) made into a dough like consistency with water (a small quantity of sugar was added to render them even more palatable), and then cut into various shapes with pastry cutters, and dried in a warm oven. Negative (unpalatable) shapes were made in a similar manner, except that no sugar was used, and a 5% aqueous solution of quinine dihydrochloride was used instead of water. The eighteen shapes made are illustrated in Fig. 2.

The monkeys were first trained to accept the experimental food in the dark in the WGTA. They were then presented with ten palatable and ten unpalatable shapes, in a counterbalanced design. For example, one monkey from a group received ten palatable crosses and ten unpalatable disks, while the other monkey received ten palatable disks and ten unpalatable crosses. All twenty shapes were presented simultaneously on a tray; the monkey was allowed to sample them at his leisure, typically taking about 10 min to do so. About 90% of the unpalatable shapes were discarded intact. The bottom of the transport cage was then covered with a cardboard sheet to prevent the animal from subsequently noticing any discarded stimuli, and the house light was switched on. For the next 20 s, the animal was shown one palatable and one unpalatable shape. Both these stimuli were manipulated by the experimenter so that the animal saw them from all possible angles. They were then placed side by side on a tray, and presented to the animal, who was permitted only one choice. This procedure was repeated daily, with a different pair of shapes being used on different days. These shapes were recombined after all nine pairs had been presented. In all, twenty choices per animal were recorded.

At the conclusion of the cross-modal study, all animals were given visual discrimination problems, using the palatable and

Fig. 1 Common (black) and maximum (stippled) extent of the lesions. For FPS $N = 3$, for PIT $N = 2$ and for AIT $N = 2$. The FPS lesion was designed to extend from the lower limits of the lunate sulcus to the superior temporal sulcus and from the lunate sulcus ventrally to the inferior occipital sulcus, thus including part of the foveal representation of Zeki's³ area V4. The AIT lesion extended anteriorly from the inferior occipital sulcus, with a lateral extent from the superior temporal sulcus to the ventral temporal lobe. The PIT plus AIT damage together constitute the traditional inferotemporal or TE lesion.

Table 1 Performance of individual subjects expressed as percentage correct on cross-modal matching and visual discrimination tasks

Animal and lesion	Cross-modal percentage corrects	P binomial two-tail test	Visual discrimination percentage corrects	P binomial two-tail test
Friend FPS	60		45	
Eunuch FPS	35	0.8	70	0.0358
Judge FPS	50		68	
Schizophrenic PIT	45	0.65	68	0.00014
Man PIT	60		78	
Fool AIT	75	0.0046	73	0.00014
Cockatoo AIT	75		73	
Jumper N	75	0.0114	73	0.00032
James N	70		76	

unpalatable shapes. Each animal had ten trials daily, using different pairs of stimulus shapes on different days, for a total of 4 d. This experiment was undertaken to see if the impairment in cross-modal matching could be attributed to a gross perceptual and/or mnemonic dysfunction within the visual modality.

Table 1 shows the results on cross-modal matching. The ability of normal monkeys to make a cross-modal match correctly, as determined by Cowey and Weiskrantz, was confirmed ($P = 0.0114$, binomial two-tailed). Both FPS and the PIT lesions impaired cross-modal matching ($P = 0.8$ and 0.65 respectively), whereas the AIT lesions did not ($P = 0.0046$).

Fig. 2 Outlines of the eighteen shapes used, as viewed vertically. Their size can be judged from the first shape (cross), which was 5 cm along its short axis.

Statistical comparison indicated that the groups differed (information statistic⁴, $2\bar{I} = 11.728$, d.f. = 3, $P < 0.01$) and that this difference was between the AIT and the normal against the FPS and PIT groups ($2\bar{I} = 11.558$, d.f. = 1, $P < 0.001$). Furthermore, the differences between the AIT and the normals and between the FPS and PIT were not significant ($2\bar{I} = 0.170$, d.f. = 2, $P > 0.9$). On the right of Table 1 the overall percentages correct on the 40 trials on four discrimination tasks are presented, along with group significance levels, showing that none of the groups was impaired. A further analysis of the results on the visual discrimination tasks is presented in Table 2. An analysis by lesion group of the number of correct and incorrect choices on trials 2–6 on the four problems revealed no significant differences in visual discrimination performance (information statistic⁴, $2\bar{I} = 8.88$, d.f. = 15, $P > 0.8$).

The finding that the AIT group succeeded in matching whereas the PIT and the FPS animals failed was somewhat surprising, especially in view of the findings in the delayed matching to sample tasks described above. One plausible explanation stems from the findings of Iwai and Mishkin⁵, that AIT lesions result in a visual mnemonic deficit, although the more posterior lesions such as the PIT and FPS result in perceptual impairments. Furthermore, Iversen⁶ has shown that the visual memory deficit in inferotemporal lesioned monkeys is greatest when visual interference occurs. She found that inferotemporal monkeys kept in darkness after learning a visual discrimination problem were as good as normal monkeys in their ability to remember the task, whereas after new visual learning, retention was

greatly reduced. On this analysis, an AIT lesion would not impair cross-modal matching since much of the task is undertaken in the dark; and interference when the house light is switched on would be minimal, since the animal's attention is fixed on the relevant stimuli. In contrast, a PIT and a FPS lesion may impair the animal by causing a subtle visual perceptual breakdown. We do not think, however, that this is very likely. All our animals were equally good (with the exception of one FPS animal) at solving the visual discrimination problems, ruling out gross visual impairment. Since it is also known that temporal cortical lesions do not cause a tactile impairment (see ref. 7 for a review), the safest conclusion is that PIT and FPS lesions, in contrast to AIT lesions, result in a disruption of the mechanism that mediates a tactile-visual match. Further work is in progress to elucidate the common damage in the FPS and PIT lesions which underlies the reported impairment. It is worth noting that both lesions interrupt visual input to a multi-modal convergence area in the depths of the superior temporal sulcus^{8,9} and also includes partial damage to the sulcus itself. One of us (M.P.) is investigating the effects of bilateral lesions in the superior temporal sulcus, using cross modal matching and related tasks. Preliminary results suggest that there is a tactile visual cross-modal matching deficit.

Table 2 Performance matrix for the visual discrimination tasks

FPS (N = 3)	PIT (N = 2)	AIT (N = 2)	Control (N = 2)	
3 5 5 3 5	3 1 4 4 2	2 3 5 1 2	3 2 2 2 2	Incorrect
9 7 7 9 7	5 7 4 4 6	6 5 3 7 6	3 4 4 4 4	Correct
2 3 4 5 6	2 3 4 5 6	2 3 4 5 6	2 3 4 5 6	Trial No.

This analysis was performed only on trials 2–6, since the animal would of necessity perform at chance on the first trial, and after the sixth trial most problems had been learned. Thus, analysis based on trials 2–6 represents a conservative estimate of performance. The normal controls were tested on only three of the four visual problems.

This work was carried out while M.P. held a Medical Research Council research scholarship; A.S. was supported in part by a Wellcome Trust scholarship. We thank Dr D. R. J. Laming for advice on statistics, S. R. Pratt for comments and Professor O. L. Zangwill for making facilities available. We also thank Mrs Sirkka-Liisa Sahgal and Miss Katherine Morris for making stimulus shapes.

Spatial and temporal contrast sensitivity of striate cortical neurones

THE human visual system detects discontinuities in the spatial or temporal pattern of light falling on the retina; it is relatively poor at detecting steady or slowly changing patterns in either domain. These insensitivities to low rates of change in space and time are not independent: a gentle gradient of illumination can be made more visible by moving it, or modulating its brightness in time. Patterns of alternating light and dark bars with a sinusoidal luminance profile across the bars—sinusoidal gratings—are commonly used to study spatial interactions in the visual system. Some of the earliest workers to use these stimuli noticed that human sensitivity to steady sinusoidal gratings of low spatial frequency is poor, but is markedly enhanced if the grating is moved or modulated in time^{1,2}.

It has often been proposed that the lateral inhibitory mechanisms responsible for the system's relative insensitivity to low spatial frequencies operate with a slower time course than excitatory mechanisms, relatively reducing the effectiveness of lateral inhibition during the presentation of time-varying stimuli^{2–6}. Adaptation studies, however, suggest that temporal modulation does not change the spatial frequency tuning of individual spatial filters ('channels') in the human visual system^{7,8}; the increased detectability of temporally modulated low spatial frequency gratings could reflect the activity of a separate population of channels, sensitive to low spatial frequencies and relatively insensitive to steady stimuli^{8,9}.

The available neurophysiological evidence is equivocal. Lateral inhibition in the receptive fields of cat retinal ganglion cells is somewhat slower than excitation from their receptive field centres^{10,11}. But at the next stage of visual processing, the lateral geniculate nucleus, there is no difference between the time courses of excitatory and inhibitory mechanisms¹². We have examined the spatial frequency tuning of single neurones in cat striate cortex to establish whether their tuning is affected by the frequency of temporal modulation: does an increase in the temporal frequency of stimulation enhance a unit's sensitivity to low spatial frequencies?

Adult cats were prepared for electrophysiological recording using techniques described elsewhere¹³. Surgery was performed under short-acting barbiturate anaesthesia (Brietal); for recording, animals were artificially ventilated with a mixture of N₂O–O₂–CO₂ (78:20:2). The eyes were stabilised with an intravenous infusion of gallamine triethiodide (Flaxedil: 10–30 mg kg⁻¹ h⁻¹), coupled with bilateral cervical sympathectomy. Pupils were dilated with homatropine, and the corneas were protected with clear contact lenses. Artificial pupils (3 mm diameter) were placed directly in front of the eyes, and supplementary lenses were chosen to focus them on a screen 114 cm distant. The activity of single neurones was recorded with tungsten-in-glass micro-electrodes¹⁴ hydraulically advanced into the cortex through a sealed chamber over a small craniotomy and durotomy. Amplification and display of action potentials were conventional; a standard pulse triggered by each spike was fed to an audiometer, from which the experimenter judged the activity of the cell.

Receptive fields were initially mapped on a tangent screen

using flashed and moving stimuli, and classified according to the criteria of Hubel and Wiesel¹⁵. The dominant eye was chosen, and a cathode-ray oscilloscope, whose mean luminance was 150 cd m⁻², and which subtended 10° × 12.5° was centred on its receptive field; the other eye was covered.

Drifting sinusoidal gratings of different spatial and temporal frequencies, optimised for orientation and direction of movement, were generated on the oscilloscope face by a PDP-11/20 digital computer. The temporal frequency of a drifting grating is the number of cycles of the grating which pass any point on the screen in 1 s; its contrast is the difference between the luminances of its brightest and dimmest points divided by their sum. For any one cell, as many as forty different gratings were used—eight spatial frequencies, each drifting at five different temporal frequencies. The computer presented the gratings once each in random order, and the experimenter adjusted the contrast of each and turned it on and off under computer control until he judged that its introduction and withdrawal caused a liminal change in the activity of the cell. When a threshold had been estimated for each of the stimuli, their order was re-randomised and they were presented again. Four estimates of each threshold were obtained in this way; the standard error of their mean was normally between 0.1 and 0.2 log units.

Fig. 1 Spatial and temporal contrast sensitivity functions of a simple cell. *a*, Spatial frequency tuning. The cell's contrast sensitivity as a function of the spatial frequency is shown for gratings drifting at three temporal frequencies. ○, 1 Hz; ●, 4 Hz; △, 16 Hz. *b*, Temporal frequency tuning. The contrast sensitivity as a function of temporal frequency is shown for gratings of three spatial frequencies. Contrast sensitivity is the reciprocal of the contrast at threshold, $(L_{max} + L_{min}) / (L_{max} - L_{min})$. ○, 0.13 cycles per degree; ●, 0.25 cycles per degree; △, 0.5 cycles per degree.

We examined the spatial frequency tuning of 48 units from 10 cats. Of these, 27 were simple, 18 complex and two non-oriented. We examined spatial frequency tuning as a function of temporal frequency in the manner described above in 26 of these units, 15 simple and 11 complex.

Figures 1 and 2 illustrate the results of two such experiments, performed on a simple cell and a complex cell recorded within 70 μm of each other. Figures 1*a* and 2*a* show that both cells were well-tuned for spatial frequency, and that the general form of their tuning curves was little affected by a 16-fold increase in temporal frequency. Neither the optimum spatial frequencies nor the relative low-frequency sensitivity was systematically changed. Although their overall sensitivity varied considerably with temporal frequency (Figs 1*b* and 2*b*) it is clear that the shapes of their temporal frequency tuning curves at different spatial frequencies were rather similar, apart from a slight tendency for the sensitivity to slow drift rates to be rather less at non-optimal spatial frequencies. This may reflect the fact that the responses of cortical cells to stimuli which are not optimal for the cell are more transient than those to optimal stimuli¹⁶.

The cells illustrated are typical: in no case did we observe

Fig. 2 Spatial and temporal contrast sensitivity functions of a complex cell. *a*, Spatial frequency tuning. \circ , 1 Hz; \bullet , 4 Hz; \triangle , 16 Hz. *b*, Temporal frequency tuning. Conventions as in Fig. 1. \circ , 0.38 cycles per degree; \bullet , 0.75 cycles per degree; \triangle , 1.5 cycles per degree.

any tendency for cells to become less well-tuned for spatial frequency at high temporal frequencies.

The results shown in Figs 1*b* and 2*b* also show that the sensitivity of the units to the velocity of stimulus movement depends on its spatial frequency. Expressed in terms of velocity in degrees per second (temporal frequency divided by spatial frequency), the cells' optima vary by a factor of eight to twelve over the range of spatial frequencies used. This contrasts with the situation when single moving bars are used as stimuli: in that case, the preferred velocity is independent of bar width¹³.

Our results may indicate that the effects of temporal modulation on human sensitivity to gratings of low spatial frequency cannot be explained by a change in the spatial frequency tuning characteristics of single neurones, unless neurones in the visual cortex of man are different from those in cat. Although we have not observed much variation among the temporal characteristics of striate neurones, it has been reported elsewhere¹⁴ that visual cortical neurones can be subdivided into a sustained group sensitive to high spatial frequencies and a transient group more sensitive to lower frequencies, which may represent the two populations of neurones required to explain the increase in low-frequency sensitivity produced by temporal modulation seen psychophysically.

It is also interesting that, since the sensitivity of units to the temporal frequency of drift does not depend on the spatial frequency of the stimulus, their selectivity in the domain of stimulus movement seems not to be for velocity but for temporal frequency, or the local rate of change in luminance with time.

Absence of fast block to polyspermy in eggs of sea urchin *Strongylocentrotus purpuratus*

SEA urchin eggs remain monospermic during fertilisation by excluding the entry of all but one sperm. Two mechanisms have been proposed to account for this exclusion. The first is a rapid alteration of the egg surface, lowering its receptivity to sperm, which occurs within a few seconds of successful contact of the fertilising sperm; this is the so-called fast block¹. This block prevents or reduces further sperm entry for the next 30 s, until the time of the cortical reaction, which establishes the second and permanent block to polyspermy. This permanent or cortical block results from the release of cortical granule proteases, elevation of the fertilisation membrane, and subsequent detachment of sperm. The existence of a cortical block has been well established by a number of investigators²⁻⁴. Although the concept is intuitively compelling, the existence of a fast block has been questioned^{5,6}, and it is supported by only one series of experiments¹.

An opportunity arose to test the hypothesis of a fast block in sea urchin eggs when we found that by using high sperm-egg ratios, untreated *Strongylocentrotus purpuratus* eggs could be made highly polyspermic. In conditions in which many sperm enter each egg, we found no change in the frequency of sperm-egg fusions after fusion of the first sperm. We conclude that there is no fast block to polyspermy in *S. purpuratus*.

S. purpuratus gametes were shed after injection of 0.5 M KCl into the body cavity. Egg jelly was removed by swirling eggs in acid seawater (adjusted to pH 5.0 with 0.1 N HCl) for 2 min. The egg suspension was then adjusted to pH 8.0 with 1 M Tris-seawater pH 8.0, and washed extensively with filtered seawater. Suspensions of eggs were inseminated and incubated before

Fig. 1 Induction of polyspermy by increasing sperm-egg ratios. Samples (1 ml) of *S. purpuratus* eggs (0.002-2.0%) were inseminated with 0.2 ml of diluted sperm. Sperm-egg suspensions were incubated for 12.5 min at 16 °C before fixation in 95% ethanol-glacial acetic acid (3:1) for 18 h with three changes of solution. Eggs were cleared in 45% acetic acid and decondensed sperm nuclei observed by phase contrast microscopy. Sperm nuclei were counted in 40-50 randomly selected eggs. Final sperm densities: \bullet , 4×10^8 ; \circ , 4×10^8 ; \square , 4×10^7 ; \blacksquare , 4×10^6 ; \triangle , 4×10^5 sperm per ml.

Fig. 2 Time course of sperm-egg fusions. *a*, samples (1 ml) of eggs were inseminated at time 0 by addition of 0.2 ml of sperm (8×10^7 per ml final). Eggs and sperm from the same sources were used throughout. Supernumerary sperm were killed by addition of 1 ml of 0.0075% SDS in seawater. This suspension was diluted with 4 ml of seawater 15 s later. Eggs were allowed to incubate before fixation as described in Fig. 1. Fertilisation was scored positive if a male pronucleus was visible within the egg. *b*, HCHO (0.037%) was substituted for SDS. All other procedures are the same as in *a*. \square , % fertilised; \bullet , number of sperm nuclei per egg (average value).

fixation. Eggs were cleared and decondensed sperm nuclei inside the eggs were counted using phase microscopy (Fig. 1).

We found that 100% polyspermy, with up to six sperm nuclei per egg, occurred in untreated *S. purpuratus* eggs fertilised at sperm-egg ratios greater than 10^4 (Fig. 1). This high level of polyspermy is normally achieved only by the use of polyspermy-inducing agents, such as nicotine or soy bean trypsin inhibitor. We believe our observations with untreated eggs result from the use of very high sperm-egg ratios, while most workers use ratios in the range 10^2 – 10^4 sperm per egg^{6,7}.

The observation that *S. purpuratus* eggs can become highly polyspermic suggests either (1) that at high enough sperm concentrations multiple sperm-egg fusions can occur before a fast block is established 2–3 s after insemination, or (2) that there is no complete fast block and sperm continue to fuse until the cortical block is established. To test these alternatives we determined when additional sperm were fusing with the egg in conditions which produced high levels of polyspermy. We added the spermicidal agent sodium dodecyl sulphate (SDS) or formaldehyde (HCHO) to a sperm-egg mixture at various times after insemination, to measure the number of fusion events which had occurred before their addition⁸. The addition of spermicidal agents at these times apparently prevents further sperm-egg fusion, but allows those sperm which have already fused to penetrate the egg and undergo nuclear decondensation. Accordingly we define sperm-egg fusion as an event which is a direct precursor of sperm penetration and nuclear decondensation, and which renders these subsequent processes insensitive to SDS or HCHO. Although we do not know the nature of the event which makes sperm penetration insensitive to SDS or HCHO, it is not simply binding of sperm to the egg surface, since hundreds of sperm bind at high sperm-egg ratios before the addition of spermicidal agents, but only a few subsequently enter the egg. It seems reasonable that the event which makes sperm penetration insensitive to SDS or HCHO is actual fusion of the sperm and egg plasma membranes.

The timing of sperm-egg fusions was assayed by adding

0.0075% SDS or 0.037% HCHO to a sperm-egg suspension at various times after the gametes were mixed, and diluting 15 s later with the addition of 2 volumes of seawater. The eggs were fixed 12.5 min after insemination to count the decondensed sperm nuclei they contained. The concentration of spermicidal agent used was the minimum necessary to prevent fertilisation (that is, no elevation of a fertilisation membrane and no decondensed sperm nuclei) when added to eggs 1 s before sperm were added. The spermicidal agents were diluted routinely before this minimum effective concentration 15 s after their addition to limit their possible effect on the eggs. Although not done routinely, dilution could be performed at 1 s without altering the results, suggesting that SDS and HCHO are both fully effective within 1 s of their addition. These agents do not cause polyspermy by themselves, since the maximum level of polyspermy attained when they were present was no more than in control eggs not exposed to SDS or HCHO.

Figure 2 represents the results of a typical experiment to determine the time of occurrence of SDS or HCHO-sensitive sperm-egg fusions at sperm-to-egg ratios which produced polyspermy. A hundred per cent fertilisation, as judged by the subsequent appearance of at least one decondensed nucleus per egg, was achieved by 3–5 s after insemination; yet sperm-egg fusion continued for 25 s more. We conclude that fusion of the first sperm does not trigger an absolute block to the fusion of additional sperm. Our results support the concept of an absolute block to subsequent sperm entry which occurs at the time of the cortical reaction, since no additional fusion events occur after this time.

Although our results rule out a complete fast block to further sperm entry, there might have been a partial fast block (that is, a reduction in the rate of sperm-egg fusions after fusion of the first sperm) which the data in Fig. 2 do not rule out. If there were a partial fast block, the rate of sperm-egg fusions, as measured in a population of eggs, would decrease after 100%

Fig. 3 The time course of sperm-egg fusions, determined over a wide range of dilutions of a single sperm suspension. At the indicated times supernumerary sperm were killed by addition of SDS and the eggs were processed as under Fig. 2. Final sperm densities: *a*, 5×10^7 ; *b*, 2.5×10^7 ; *c*, 1.25×10^7 ; *d*, 5×10^6 ; *e*, 2.5×10^6 per ml.

fertilisation had been achieved, due to the lowered receptivity of the egg surface triggered by the first sperm. In the absence of any fast block, sperm-egg fusions would occur at the same rate before and after 100% fertilisation. The consistent result of experiments to test these alternatives critically is presented in Fig. 3. The rate of sperm-egg fusions was linear with time and proportional to the sperm-egg ratio. Moreover, in each case, the rate was identical before and after 100% fertilisation. We conclude that there is no change in egg receptivity to further sperm for at least 12 s after fusion of the first sperm, or no fast block.

Our conclusion that there is no fast block presents a paradox. As stated earlier, there are hundreds of sperm binding to the egg surface between the time of insemination and the complete cortical block. Without a fast block, how are all but a few of these supernumerary sperm excluded during this interval? We propose that the egg surface and surface coats act as filters to limit the fusion of these additional sperm. One such filter is the jelly coat of the egg, as proposed by Runnstrom and Manelli⁷. We have also found that in *S. purpuratus* eggs the intact jelly coat reduces the level of polyspermy obtained at moderate sperm-egg ratios below the level for eggs without a jelly coat. Even with the jelly layer removed, however, the number of bound sperm which can enter the egg is severely limited. The additional barrier may be a property of the egg's vitelline layer or the egg plasma membrane, which provide a limited number of effective sites or a time-delay barrier for sperm-egg fusion.

We thank Drs David Epel and Meredith Gould-Somero for reading the manuscript. This work was supported by NIH fellowship grants to both authors and an NSF grant to Dr Epel.

Factors released from sea urchin eggs affect cyclic nucleotide metabolism in sperm

Cyclic nucleotide phosphodiesterase inhibitors and exogenous cyclic AMP or cyclic GMP can increase or maintain mammalian sperm motility, respiration rate and fructolytic rate¹⁻⁷. Sperm from various species have been shown to contain high activities of cyclic AMP-dependent protein kinase⁸⁻¹⁰, guanylate cyclase^{11,12}, cyclic nucleotide phosphodiesterase¹¹, phosphoprotein phosphatase¹³, and adenylate cyclase^{11,14}. These and other observations have led to speculation that cyclic nucleotides regulate or modulate sperm motility and metabolism¹⁵, and that this modulation may occur during the processes of capacitation or fertilisation¹⁶⁻¹⁷. The latter hypothesis requires that factors from the female or from the ovum itself alter sperm cyclic nucleotide levels. Until now there has been no demonstration of a naturally occurring factor of animal origin that can substantially change cyclic nucleotide levels in sperm¹⁵. The purpose of this study was to determine whether or not there are factors released from eggs that can alter sperm cyclic nucleotide levels. Gametes from sea urchins were used because both eggs and sperm can be obtained in large quantities, and

because factors released from sea urchin eggs have been known for some years to alter sea urchin sperm motility¹⁸⁻²⁰ and respiration^{20,21}.

Eggs and sperm were collected and washed as described previously²². Factors released from eggs (FRE) were obtained from the sea urchins, *Strongylocentrotus purpuratus* or *Lytechinus pictus*, by allowing eggs (10-20 mg wet weight ml⁻¹) to stand in a medium of simulated seawater²² for various times at 15-17 °C. The supernatant fluid above the eggs ('egg water') was collected by gentle centrifugation in a clinical centrifuge at 15-17 °C. The supernatant fluid containing FRE was added to incubation tubes containing artificial seawater with or without theophylline. To start the incubation (15-17 °C), 0.25 ml sperm suspended in artificial seawater (40-80 mg wet weight ml⁻¹) was added to each incubation tube. The incubations were terminated by addition of 1.0 ml 0.3 N perchloric acid containing traces of cyclic ³H-AMP and cyclic ³H-GMP to monitor recoveries. Cyclic AMP and cyclic GMP were purified and assayed as described elsewhere²³⁻²⁷.

Cyclic AMP concentrations in *S. purpuratus* sperm were increased approximately twofold by 1.5 mM theophylline after 1-min incubation (Table 1). FRE alone increased sperm cyclic AMP concentrations by about sevenfold, and the combination of FRE plus theophylline increased cyclic AMP concentration 100-fold. On the other hand, cyclic GMP in *S. purpuratus* sperm was decreased by about 40% by FRE. In contrast to their effects on cyclic AMP concentrations, theophylline plus FRE did not exert synergistic effects on cyclic GMP concentrations. Effects similar to those observed with FRE plus theophylline were observed with FRE plus 1-methyl-3-isobutylxanthine, another phosphodiesterase inhibitor.

Table 1 Effect of FRE from *S. purpuratus* on cyclic nucleotides in *S. purpuratus* sperm

FRE	Theophylline	Cyclic AMP (nmol per g wet weight sperm)	Cyclic GMP (nmol per g wet weight sperm)
None	None	2.5±0.7	0.76±0.12
None	1.5 mM	4.7±0.7	1.0±0.16
0.1 ml	None	16.6±2.0	0.46±0.04
0.1 ml	1.5 mM	267±26	1.13±0.16

Number of observations six; values represent mean ± s.e.m.

All sperm incubations were for 1 min at 15-17 °C.

Time zero cyclic AMP concentrations were 2.9±0.9 (*n* = 12) and those for cyclic GMP were 0.83±0.13 (*n* = 12) nmol per g wet weight. Time zero values were obtained by the addition of 0.3 N perchloric acid to incubation mixture before addition of the sperm.

Synergistic effects of FRE and theophylline on cyclic AMP content were also observed in sperm from *L. pictus*, although the changes were of smaller magnitude than in *S. purpuratus* sperm (Table 2). FRE from either *L. pictus* or *S. purpuratus* eggs in combination with theophylline increased cyclic AMP more than theophylline alone. Unlike the situation with *S. purpuratus* sperm, however, FRE alone did not increase cyclic AMP in *L. pictus* sperm (Table 2).

In addition to being increased by FRE and theophylline, cyclic AMP concentrations in *L. pictus* sperm were also increased by diluting the sperm in simulated seawater. Dilution of the sperm in the incubation mixture increased sperm cyclic AMP by about twofold by 1 min after dilution (Table 2). The increase was transient; by 10 min after dilution, concentrations were equal to or less than those at time zero. Such an effect of dilution was not seen with *S. purpuratus* sperm.

Because of the greater FRE-induced changes in cyclic AMP, *S. purpuratus* sperm were used in studies designed to partially characterise the cyclic AMP-elevating factor(s) present in FRE. The cyclic AMP response to increasing amounts of FRE in the presence of 1.5 mM theophylline seemed to be hyperbolic (data not shown). The same batch of FRE that was used to obtain the data in Table 1 caused a half-maximal increase in sperm cyclic AMP when about 10 µl were added to the incuba-

Table 2 Effects of FRE from *L. pictus* and of *S. purpuratus* on cyclic AMP in *L. pictus* sperm

	Theophylline (mM)	Cyclic AMP (nmol per g wet weight sperm)		
		1 min	10 min	30 min
No FRE	0	9.3±1.1	2.4±0.3	1.3±0.01
	0.15	13.4±1.1	3.4±0.3	—
	0.38	16.7±1.5	3.8±0.5	—
	1.5	21.1±1.6	5.1±1.4	3.8±0.6
<i>L. pictus</i> FRE (0.1 ml)	0	10.2±0.4	3.1±0.2	1.6±0.06
	0.15	22.4±1.7	4.9±0.3	—
	0.38	27.6±2.4	6.3±0.4	—
	1.5	40.5±3.7	9.6±0.8	5.8±0.2
<i>S. purpuratus</i> FRE (0.1 ml)	0	9.9±0.5	3.2±0.5	1.2±0.1
	0.15	17.3±0.9	4.0±0.2	—
	0.38	23.9±1.5	5.5±0.3	—
	1.5	35.0±2.2	8.3±0.4	5.5±0.8

Values represent mean ± s.e.m. of six observations at 1 and 10 min and of four observations at 30 min.

Time zero (see Table 1) cyclic AMP level in these sperm was 4.1 ± 2.1 ($n = 11$).

tion mixture. No increases were detected in cyclic GMP with up to 200 µl FRE in the presence of theophylline.

When a saturating amount of FRE was tested, there was some loss of cyclic AMP-elevating activity after dialysis, complete loss after ashing, but no significant loss after boiling FRE for 30 min. Two peaks of cyclic AMP-elevating activity were detected after filtration of 10 ml FRE on Sephadex G-50 columns (2.6 × 34 cm) equilibrated with simulated seawater. One of these peaks migrated in the void volume and was non-dialysable, whereas the other was retained by the column.

The mechanism of the FRE-induced elevation in cyclic AMP and reduction in cyclic GMP remains to be clarified. Direct stimulation of sperm adenylate cyclase by FRE in broken cell preparations has not been demonstrable, but extensive variations in assay conditions have not been examined. On the other hand, a potent inhibitor of sea urchin sperm guanylate cyclase in cell-free systems has been detected as a component of FRE

Table 3 Inhibition of sea urchin sperm guanylate cyclase by FRE

FRE (µl)	Guanylate cyclase activity (pmol cyclic GMP formed min ⁻¹)
0	744
5	527
10	409
25	299
50	263
100	211

Assay mixture contained 19.2 mM sodium azide, 12 mM theophylline, 0.45 mM GTP, 0.9 mM MnCl₂, 5 × 10⁶ c.p.m. ³H-GTP (5.6 Ci mmol⁻¹), the indicated amounts of FRE, 30 mM triethanolamine buffer at pH 7.8, and washed particles from 0.5 mg (wet weight) of sea urchin sperm²². The cyclic ³H-GMP formed during 15 min at 30 °C was determined as described elsewhere¹².

(Table 3). This material is stable to boiling, non-dialysable, and destroyed by ashing. The inhibitor is not adsorbed by charcoal and is not extracted from the simulated seawater by benzene or ether. Its inhibitory potency is much greater at low than at high sperm protein concentrations. Whether or not the inhibitor has any selectivity for guanylate cyclase over other enzymes, and whether or not it is the same as the non-dialysable substance(s) that increase cyclic AMP concentrations is not yet known.

These data constitute the first demonstration of alterations of sperm cyclic nucleotide concentrations by possible natural effectors. The potencies of the substance(s) that inhibit guanylate cyclase and increase cyclic AMP concentrations in sperm from sea urchins raise the possibility of their physiological importance in regulating sperm motility and metabolism. The possible release of similar factors from eggs of other species should be explored.

Taxis to a conjugation-inducing substance in the ciliate *Blepharisma*

FOR conjugation of *Blepharisma intermedium* to take place interaction of soluble gamones with the cells is essential for union between complementary mating types I and II (refs 1 and 2). Type I cells excrete gamone 1 which transforms type II cells so that they can unite. Type II cells excrete gamone 2 which similarly transforms type I cells. Moreover, each gamone promotes the production of the other. Gamone 1, blepharismone, is a glycoprotein of molecular weight 20,000 (refs 3 and 4). Gamone 2, blepharismone, is calcium 3-(2'-formylamino-5'-hydroxybenzoyl) lactate⁵.

In a preliminary observation, in which a capillary containing gamone was placed in a cell suspension, type I cells were attracted by gamone 2. The observation has been confirmed here by the improved method using a microscope slide and coverslip (Fig. 1).

Clones A₁ (albino), N, D₃s and 4a of *B. intermedium* were used. A₁ and N were mating type I and D₃s and 4a were mating type II. The general techniques for the culture and handling of cells have been described elsewhere¹. Unless specified, cells were washed with and suspended in buffer¹ and starved for at least 1 d before use. Gamone 1 was purified as indicated³. Synthetic gamone 2 was supplied by Dr T. Tokoroyama, Osaka City University, and purified before use^{5,6}. One unit of gamone activity was defined as the smallest amount of gamone activity that can induce homotypic cell union in 500 cells suspended in 1 ml buffer¹. It corresponds to activities of 0.06 and 1.0 ng of purified gamones 1 and 2, respectively.

The taxis value was defined as described in Table 1 and the semi-quantitative measurement showed that type I cells were

Fig. 1 Taxis of type I (A_1) cells to gamone 2. $10 \mu\text{l}$ of type I (A_1) cell suspension and $1 \mu\text{l}$ of cell-free fluid of the same cell suspension containing gamone 2 of $1,000 \text{ U ml}^{-1}$ (a) or none (b) were placed on a microscope slide and covered by a coverslip lifted 0.16 mm by spacers. The two drops were arranged so that, after covering, the smaller, satellite drop was situated very close to the left side of the larger, cell-containing drop. The two drops were then merged together by slightly moving the coverslip. Photographed after 30 min. Diameters of the disks were approximately 5 mm .

attracted by gamone 2 but not by gamone 1, while type II cells were attracted by neither (Table 1). The results were always reproduced in at least duplicate experiments.

Taxis values of type I (A_1) cells to different concentrations of gamone 2 are shown in Fig. 2. The threshold concentration of gamone 2 for the attraction may be estimated to be $10^{-6} \text{ U ml}^{-1}$ or $10^{-6} \text{ ng ml}^{-1}$. The sensitivity of type I cells to gamone 2 is, therefore, much higher in taxis than in the cell union.

Well-fed cells which are known not to respond to gamone 2 by cell union (H.H. and A.M., unpublished) were also not attracted by gamone 2. When such cells were washed, suspended in the buffer and observed during 9 h starvation, the taxis value suddenly increased between the third and the fourth hour reaching a maximum at the fourth hour (Fig. 3). Cell union also appeared after 4 h (Fig. 3). As the induction of cell union took 1 h in starved A_1 cells, the results indicate that the ability of cells to respond to gamone 2 by taxis and by cell union appears at nearly the same time, after 3 h of starvation.

The treatment of A_1 cells by cycloheximide ($20 \mu\text{g ml}^{-1}$, 2.5 h) did not change the ability of cells to be attracted by gamone 2. This treatment completely inhibits protein synthesis and the formation of cell union, which requires protein synthesis⁷ (H.H. and A.M., unpublished), suggesting that cell union and

Fig. 2 Taxis values of type I (A_1) cells to different concentrations of gamone 2.

Table 1 Taxis values of mating types I and II of *B. intermedium* to their gamones

Attractants	Cells			
	Mating type I		Mating type II	
	A_1	N	4a	D_{3s}
Gamone 1	-0.03	0.00	0.00	0.06
Gamone 2	0.84	0.61	0.01	-0.03
Control (cell-free fluid)	-0.01	0.02	0.01	-0.01

Taxis values were obtained by the similar apparatus in Fig. 1, using gamones 1 and 2 of $4,000$ and $1,000 \text{ U ml}^{-1}$ respectively except the one marked by * in which gamone 1 was 130 U ml^{-1} . After 30 min from mergence of two drops, the cells were counted in each half of the drop parted evenly by a plane perpendicular to the line which passes through the centre of the cell-containing drop and the merging point of the two drops. The attraction of cells was expressed by the taxis value, $(a-b)/(a+b)$, where a and b were the number of cells in one half containing the merging point and the number of cells in the other half. Each value was the average of the values obtained by four experiments in which the relative position of the drops was changed by rotating the axis of the cell-containing drop, which was perpendicular to the surface of the coverslip, by 0° , 90° , 180° and 270° respectively.

taxis are independent. Whether gamone 2 receptors are different in these two responses is still to be determined.

Positive taxis of ciliates to the complementary mating type or its specific product has been reported only in *Tokophrya*. In this sessile ciliate, complementary mating types, if placed within a certain distance, orient and stretch toward each other (T. M. Sonneborn, personal communication, cited in ref. 2). In view of the obvious adaptive value of a sexual attractant

Fig. 3 Gamone taxis and gamone-induced cell union during starvation of well-fed type I (A_1) cells. Taxis values were measured on samples taken at different times during starvation. United cells were observed on a sample to which gamone 2 was added (800 U ml^{-1}) at the time indicated by the arrow. ●, Taxis to the cell-free fluid with gamone 2 ($1,000 \text{ U ml}^{-1}$); ○, taxis to the cell-free fluid without gamone 2; △, percentage of cell number in united cells.

and its general occurrence in eukaryotes, it is likely that more examples of mating type specific attraction will be found in ciliates.

The development of gamone taxis only in type I cells of *B. intermedium* may be compared with the fact that in many organisms only one of the two sexes attracts the other by a pheromone. The finding that type I cells respond to extremely low concentrations of gamone 2 demonstrates that ciliates have a highly sensitive sensory mechanism to specific molecules,

and thus introduces a new system of chemoreception amenable to molecular analysis.

Biogenesis of chemotactic molecules by the arachidonate lipoxygenase system of platelets

BLOOD platelets contain two aggregation-activated enzyme systems that oxygenate arachidonic acid. One system is a cyclo-oxygenase that converts arachidonic acid into the biologically active endoperoxide prostaglandin G_2 (PGG_2), a precursor of classical prostaglandins E_2 (PGE_2) and $F_{2\alpha}$ ($PGF_{2\alpha}$), as well as several non-prostanoid hydroxy fatty acids¹. The second aggregation-activated platelet enzyme is a lipoxygenase that transforms arachidonic acid into 12-L-hydroxy-5,8,10,14-eicosatetraenoic acid (HETE)².

Fig. 1 TLC of the ether-extractable products obtained after incubation of 100 μ g of arachidonic acid with soluble platelet lipoxygenase (from 40 ml of human blood). Incubation was conducted in 0.1 M Tris-HCl/0.1 M K_2HPO_4 buffer (pH 8.2) at 30 °C for 90 min. Total reaction volume was 1 ml. Plates of silica gel 60 (Merck) (activated at 110 °C for 2 h) were developed to 15 cm with isopropyl ether-ethyl acetate-acetic acid (80:20:3 v/v). Chemotactic activity was assayed for one-fifth of each indicated fraction of the chromatogram and is expressed as a chemotactic index $CI = (C_a - C_b)/(C_c - C_b)$, where C_a , C_b and C_c are the average number of polymorphonuclear leukocyte indicator cells per $\times 430$ field attracted by the test agent (C_a), positive control: cell-free *Escherichia coli* growth medium (C_b), and buffer medium (C_c). Chemotaxis assays were performed in duplicate and five fields were counted and averaged for each assay. Chemotactic activity was primarily associated with the iodine-positive band at R_f 0.57 which was subsequently identified as HETE (see text). The concentration of HETE subjected to chemotaxis measurements was approximately 1 μ g ml^{-1} as estimated by GLC. Arrows indicate R_f values for lipid standards, a, PGE_1 , PGE_2 (R_f 0.07); b, ricinoleic acid (R_f 0.57); c, arachidonyl alcohol (R_f 0.66); d, arachidonic acid (R_f 0.72).

Although HETE is produced in significant quantities by aggregated platelets, no biological function for this compound has been reported. We now have evidence that HETE is a potent mediator of neutrophil chemotaxis.

We suggested³ that oxygenated arachidonate products may be the chemotactic mediators released by aggregated blood platelets⁴ because identical conditions are required for both arachidonate oxygenation and the generation of chemotactic activity^{2,4}. Since we had demonstrated that photo-oxidised arachidonic acid is chemotactic for neutrophils⁵, this hypothesis seemed even more tenable.

To test this hypothesis, chemotactic factor was generated by incubating the soluble lipoxygenase fraction² of human blood platelets with pure arachidonic acid. The chemotactic activity of the reaction mixture and its subsequent fractions was measured as before⁵, using non-autologous human polymorphonuclear leukocytes as indicator cells. After incubation, the products were acidified (pH 4) with 2 M citric acid and extracted into diethyl ether². All chemotactic activity was extracted into the ether phase, which was dried under nitrogen, resuspended in methanol, and subjected to thin-layer chromatography (TLC). All bands that could be visualised with the aid of 254-nm radiation, iodine vapour, and ninhydrin were removed from the chromatogram and tested for chemotactic activity.

As Fig. 1 shows, chemotactic activity was almost exclusively associated with an iodine-positive band at R_f 0.57. This material, evident as a dark absorption band under 254-nm illumination, exhibited no reaction with ninhydrin. The chemotactic band was clearly separated from authentic samples of PGE_1 , PGE_2 , arachidonyl alcohol, and arachidonic acid, but comigrated with ricinoleic acid. An iodine-positive band corresponding to unreacted arachidonic acid was also detected on the chromatogram. Another incubation, identical to the experiment described in Fig. 1 except for the addition of indomethacin (1 μ g ml^{-1}), gave a chemotactic profile almost identical to that shown in Fig. 1. This result indicated that the reactions studied were not due to the action of the platelet cyclo-oxygenase system which is inhibited by indomethacin at these concentrations¹. Other incubations which omitted the lipoxygenase or included lipoxygenase boiled for 30 min were not chemotactic and did not yield the R_f 0.57 band. These data suggested that platelet lipoxygenase was converting arachidonic acid into a chemotactic hydroxy fatty acid, probably HETE.

The presence of HETE was indicated by gas-liquid chromatography (GLC) (3% OV-225 on 120/100 Chromasorb WAW with column temperature 220 °C) of the active compound after catalytic reduction (H_2 -Pd on barium sulphate) and methylation (ethereal diazomethane). A single elution peak was observed which had the retention time of the methyl ester of a 20-carbon hydroxy fatty acid. The identity of the chemotactic material as HETE was confirmed by GLC-mass spectrometry (MS). A mass spectrometer (Finnigan 3300) fitted with a column of 1% OV-17 was programmed from 160–240 °C at 8 °C per min to obtain an electron impact fragmentation pattern of the reduced, methylated unknown. Prominent peaks at m/e 229, 200 and 197 were obtained which corresponded precisely to the reported mass spectrum of reduced, methylated HETE². The molecular ion ($M=342$) was absent.

To examine further the conditions required for the synthesis of chemotactic mediators, a series of incubations of platelets and platelet components with arachidonic acid was evaluated for chemotactic products using the same protocol as in Fig. 1. As Table 1 shows, chemotactic activity was always associated with the occurrence of an I_2 -positive TLC band at R_f 0.57 which had the GLC properties of a 20-carbon hydroxy fatty acid, indicating that HETE was the only chemotactic mediator elaborated by platelets.

Table 1 also indicates that both arachidonic acid and platelet-free serum function as prochemotactic substrates

Table 1 Reaction matrix for incubations conducted as described in Fig. 1

	Arachidonic acid (100 µg)	LPS (1 mg)	Platelet-free plasma (100 µl)
Whole platelets	+	+	+
Soluble lipoxigenase	+	—	+
Platelet acid extract	+	ND	+
Arachidonic acid, 100 µg	—	—	—
<i>S. typhosa</i> lipopolysaccharide 1 mg	—	—	—

The products of each incubation were worked up and assayed for chemotactic activity as outlined in Fig. 1 and the text. + indicates that HETE was the major chemotactic product as evidenced by TLC and GLC analysis. — denotes the absence of chemotactic products. Whole platelets², soluble lipoxigenase³, and platelet sulphuric acid extract⁶ were prepared from 40 ml of blood (0.1 mg platelet protein) according to the referenced procedures. Platelet-free plasma (PFP) was obtained by differential centrifugation of human blood⁴. Indicated quantities of arachidonic acid, LPS and PFP are for 1-ml incubation volumes. ND, not determined.

for any of the platelet fractions. This circumstance raises the possibility that arachidonic acid is the prochemotactic factor observed¹ in platelet-free plasma. Furthermore, the failure of *Salmonella typhosa* lipopolysaccharide (LPS) to generate chemotactic activity with soluble lipoxigenase suggests that LPS-generated chemotactic activity requires both lipoxigenase and arachidonic acid as found in platelet membranes, for example, whole platelets × LPS (Table 1).

HETE was also identified by TLC and GLC-MS as a component of the chemotactic material generated by ultraviolet photo-oxidation of arachidonic acid⁵. This observation indicates that non-enzymatic oxidation of arachidonic acid can generate a biological chemotactic mediator without intervention of either platelet lipoxigenase or the complement immune system. The status of complement components in chemotaxis is still an open question, especially in view of the observation that a crystalline preparation of the presumably chemotactic C5a was not chemotactic for neutrophils or macrophages⁶.

On the basis of our results, we propose that the platelet lipoxigenase system functions in a complementary fashion with the cyclo-oxygenase system to provide chemotactic, vasoactive, and platelet-aggregating factors during haemostasis. The likelihood of other biological activities for products of the platelet endoperoxidase and hydroperoxidase seems to be great and merits further investigation.

We thank Dr David Rosenthal for performing the mass spectral analyses, and Ms Linda Kohl and Ms Mary Alice Lipscomb for assistance. This work was supported by grants from the National Institutes of Health and the Veterans Administration.

Thymus-like lymph node in nude mice

PANTELOURIS has reported¹ that 1 out of 60 autopsied nude mice possessed a suspected normal thymus, but histological examination was not possible. Here, we report on five nude mice with distinct lobulated thymus-like organs in the thymus area, but which can be shown to be lymph nodes, rather than thymus.

Our nude mice were maintained by mating male *nu/nu* homozygotes with female *nu/+* heterozygotes (of outbred Swiss mouse background) at the veterinary Resources Branch, National Institutes of Health, Bethesda, Maryland. We have seen previously white lobulated lymphoid tissues, whose overall appearance is that of a 'normal thymus', in 5 out of 74 nude mice of 3–5 months of age. These mice were experimentally infected with either *Trichinella spiralis* or *Schistosoma mansoni* and were housed in specific pathogen-free conditions. Histologically these thymus-like tissues were lacking in Hassall's cor-

Fig. 1 No Hassall's corpuscles or thymic epithelial cells, but proliferative lymphocytes and reticuloendothelial cells were seen in this tissue (haematoxylin and eosin stain, ×300).

puscles and thymic epithelial cells. Active proliferation of lymphocytes, histocytes, and reticuloendothelial cells was evident.

In the cortex and medulla (Fig. 1) lymphoid follicles medullary sinuses and numerous plasma cells were also observed. These observations suggest that these tissues are active lymph nodes rather than normal thymus.

We have no real evidence to suggest that it is the pre-lymphoid thymic rudiment that is repopulated by the antigen-activated lymphocytes and histocytes, although this remains a possibility. These lymph nodes may be simply the anterior mediastinal or tracheobronchial lymph nodes that are greatly enlarged due to the proliferated immunolymphocytes and reticulendothelial cells, resulting from constant antigenic stimulation.

If the nude mice were born with a genuine thymus, one would expect to see the presence of functional T cells. Thus, spleen cells from the *Trichinella*-infected nude mice with suspected thymuses, infected and non-infected *nu/+* heterozygotes and typical nude mice without thymuses, were studied in response to phytohaemagglutinin (PHA), and *Salmonella typhimurium* lipopolysaccharide (LPS). These materials are generally accepted as mitogens for mouse T and B cells, respectively. The experiments were done in triplicate. No functional T cells were found, but B cells were demonstrated in the nude mice bearing suspected thymuses (Table 1). Since, however, crossing over

Unexpectedly rapid action of human interferon in physiological conditions

THE progression of many viral infections can be affected by the administration of exogenous interferon or the production of endogenous interferon^{1,2}, the concentration of which is greatest at the site of infection^{3,4}. Therapy with interferon generally requires large amounts^{5,6} presumably to allow for diffusion to the site. Model studies of this phenomenon *in vitro* have usually been carried out in the non-physiological conditions of relatively low concentrations of interferon and room temperature⁷⁻⁹. To understand better the factors that govern the local protective action of interferon, we have done model experiments in tissue culture to define the time and concentration variables under strict simulation of body temperature by carrying out all manipulations in a 37 °C water bath.

Duplicate HR203 human foreskin fibroblast cells were incubated in tubes 13 × 100 mm with prewarmed human leukocyte interferon (from the Antiviral Substances Program, NIAID)¹⁰, diluted in 0.5 ml Eagle's medium containing 2% foetal bovine serum. At various times the interferon was removed, and the cultures were washed four times with warm Earle's balanced salt solution and challenged with a Sindbis virus to cell input multiplicity of infection of 20:1. After 1 h for virus adsorption, cultures were washed three times and incubated for 18 h before culture fluids were assayed for viral haemagglutinin (HA).

Contrary to previous observations made in less physiological conditions⁷⁻⁹, a 30-min exposure of cells to interferon resulted in a high, although not maximal, interferon titre (Fig. 1a). Maximum titre was attained when the virus challenge was applied after 2–4 h of interferon treatment.

Shorter exposures to interferon were tried next. Figure 1b shows that a 1-min exposure resulted in almost the same interferon titre as that following 30 min of exposure. Similar results were obtained when the temperature was varied between

34.5 °C (temperature of upper respiratory tract) and 40 °C for a 5-min exposure.

To determine the effect of various concentrations of interferon on the level of resistance in the human cell cultures we applied either 10 U ml⁻¹, 30 U ml⁻¹ or 300 U ml⁻¹ of interferon to different cultures for various times before virus challenge. As Fig. 2 shows, the level of early antiviral activity was proportional to the concentration of interferon applied. Thus interferon at a concentration of more than 10 U ml⁻¹ was required to initiate the development of the early appearing resistance (8–16-fold inhibition) which is strong enough to be significant biologically.

Figure 2 suggests that resistance develops very slowly between 1 and 20 min of cellular reaction with interferon. Further study is required to understand the mechanism of this lag before the beginning of a second rise in cellular resistance, which leads to a higher and stable level of resistance⁸.

Several characteristics of the early developing antiviral activity suggest that it was induced by the interferon rather than by an extraneous substance. Its rapid development was species

Fig. 1 Development of interferon activity in HR203 cells challenged at various times after exposure to human interferon. The cultures were incubated with interferon dilutions for the times indicated, washed and challenged with virus. Interferon titres are expressed at the highest dilution which inhibited the virus yield threefold.

Fig. 2 Effect of interferon concentration on the level of rapidly developing resistance. Interferon was incubated with cultures for the times indicated before virus challenge. ●, 10 U ml⁻¹; ○, 30 U ml⁻¹; +, 100 U ml⁻¹.

specific, occurring in several strains of human diploid cells but not in mouse L cells. It was induced by both human leukocyte interferon and human fibroblast interferon. The same effect was observed in mouse L cells after a 5-min application of crude or semi-purified (10^7 U mg⁻¹ of protein) mouse interferon. The resistance manifested lack of viral specificity in that both vesicular stomatitis virus and the picornavirus, GD 7, were inhibited. Preincubation of the interferon with antibody to human interferon (obtained from Dr C. Anfinsen) or inhibition of RNA synthesis by actinomycin D prevented the development of early resistance.

The effect we have found is distinct from that reported when a brief exposure of cells in the cold to interferon, followed by prolonged incubation at 37 °C, was required for the development of antiviral activity¹¹⁻¹³. For example, prolonged incubation at 37 °C was not needed for the development of rapid resistance. Also, unlike the previous example, the reaction between interferon and cells at 37 °C seems to be due to direct induction of resistance. It is possible that in the cold the initial interaction of interferon with cells does not induce antiviral activity from the original binding site. The small amount of initially cell-bound interferon may simply serve as a reservoir of interferon during washing. Subsequently at 37 °C the interferon slowly elutes from the cells into the medium and then reacts with the cells to induce resistance¹⁴. In contrast, in the warm conditions we used, preliminary experiments involving antibody to interferon and repeated washings¹⁴ indicate that this type of cellular binding and subsequent elution are not required for development of rapid resistance.

Resistance to virus challenge after brief exposure to interferon does not necessarily mean that the resistance is established at the moment of virus challenge because several viruses, including Sindbis, may be inhibited when interferon is applied to cells as late as 2 h after virus^{15,16}. Nevertheless our preliminary experiments indicate that the messenger RNA for the resistance-inducing protein is transcribed as early as 30 min after a 5-min exposure of cells to 300 U interferon. Since translation of this mRNA is very rapid¹⁷ resistance probably develops after about 30 min.

To investigate whether concentrations of interferon sufficiently high for rapid effect *in vivo* occur, we estimated concentrations in the extracellular fluid around producing cells *in vivo*. We assumed that (1) a single infected cell releases its interferon into the surrounding intercellular space over a period of 6 h; (2) the half life of interferon in the extracellular fluid is similar to the rapid turnover phase in serum, that is, 10 min (ref. 3); (3) the volume of extracellular space surrounding a cell in a solid tissue varies from 12 to 120 μm^3 , and (4) that the interferon production *in vivo* may cover the same range as in cell

culture, that is 10–10,000 U ml⁻¹ in cell cultures or 0.00005–0.05 U per cell. Thus an estimated concentration of 3,000–30,000,000 U ml⁻¹ occurs in the intercellular space surrounding an interferon-producing cell *in vivo*. These levels are much more than the minimum of 10–30 U ml⁻¹ required to induce early resistance.

The biological significance of this rapid effect is clear. *In vivo*, the infected cell frequently produces both virus and interferon. A substantial lead of development of host resistance over the spreading virus would be provided by a rapid action of the interferon on surrounding cells since virus requires at least 1 h for adsorption, penetration and uncoating. This early defence would be less effective in conditions of minimal or late interferon production, low sensitivity of virus to interferon and a large volume of extracellular fluid.

The rapid action of interferon on cells has several additional implications. Is it analogous to the moderately rapid action of certain polypeptide hormones on cells^{2,18}? Also is it possible that the brief reaction induces a cellular event which, 30 min later, leads to derepression of the cistron encoded for the antiviral protein¹⁹? Study of the initial cellular event could yield information about the step(s) leading to derepression. Finally, can treatment of viral infections with interferon be improved by methods which deliver sufficient interferon to the site of infection to induce this rapid resistance?

Immunity to Marek's disease induced by glutaraldehyde-treated cells of Marek's disease lymphoblastoid cell lines

MAREK'S disease (MD) is a common neoplastic disease of the domestic fowl caused by a herpesvirus (MDV). It is controlled in the field by vaccination with artificially attenuated strains of MDV, or more commonly with the antigenically related herpesvirus of turkeys (HVT)¹. The nature of the immune prophylaxis is not clear; protective immunity may be directed against MDV, against the development of tumours, or both. One way in which vaccination may exert its effect is by influencing the spread of MDV within the body². In contrast, infected birds may occasionally recover after showing signs of MD clinically, and in some birds MD lymphoproliferative lesions regress³, so it is likely that there is also an anti-tumour immune reaction. We have sought evidence for anti-tumour immunity in experimentally immunised birds.

MDV infection of chick kidney cells (CKCs) *in vitro* results in the expression of a number of nuclear, cytoplasmic and membrane antigens which can be visualised by immunofluorescence. Similar antigens occur on only a small proportion of MD lymphoma cells and MD lymphoblastoid line cells (about 10³ and 10 per million cells, respectively, in this study). The lymphoblastoid line cells and a variable (2–35%) proportion of MD lymphoma cells have other surface antigens which, because they occur only on cells which are thought to represent the malignant component of MD lymphomas, have been regarded as tumour specific antigens^{4,5}. The cells of lymphoblastoid lines from MD lymphomas contain the viral genome⁶, and the tumour specific antigens may be virally determined. Nevertheless it is possible to distinguish between viral antigens (as exemplified by MDV infection of CKCs) and tumour specific antigens (occurring only on non-productively infected lymphoblasts).

Lymphoblastoid line cells were used as a source of tumour specific antigens relatively uncontaminated with the known viral antigens, and CKCs infected *in vitro* with MDV were used as a source of these viral antigens. Glutaraldehyde is known to preserve or enhance the immunogenicity of antigenic structures⁷, and it was found to abolish the infectivity of MDV-infected cells in the conditions of this experiment. The induction

of tumour immunity in mice using glutaraldehyde-treated tumour cells has been reported for BALB/c tumours induced by methyl cholanthrene in BALB/c mice⁸. We have found that protection against MD can be achieved by immunisation with glutaraldehyde-treated lymphoblastoid lines as well as with similarly treated MDV-infected CKCs.

Groups of about 25 HPRS Rhode Island Red chickens were immunised (Table 1) with glutaraldehyde-inactivated tumour cells, infected lymphocytes, normal lymphocytes, lymphoblastoid cell lines or infected CKCs. A control group received no treatment, and another group was vaccinated with a standard MD vaccine (HVT). Immunised chickens were exposed to MDV at 55 d of age by mixing with birds which had been inoculated with MDV (HPRS 16 strain) 30 d previously, and which were actively shedding virulent virus. Mortality was observed until the birds were 230 d old. Birds which died from causes other than MD were eliminated from consideration. Diagnosis of MD as the cause of death was made on the basis of gross and histological visceral and neural lesions characteristic of MD⁹. The χ^2 test (with Yates's correction) was used to compare mortality in immunised groups with that of untreated birds (group F).

The results are shown in Fig. 1. As expected, birds which had been vaccinated with HVT or immunised with inactivated MDV infected CKCs were significantly protected against MD. Group G suffered a mortality of nine out of 22 ($\chi^2 = 5.54$) and group E of 5/19 ($\chi^2 = 9.96$) compared with group F (19/24). Group D, immunised with the lymphoblastoid cell lines, had a mortality of 10/23 ($\chi^2 = 4.91$). Mortality rates for the two individual cell lines were 6/13 ($\chi^2 = 2.82$) and 4/10 ($\chi^2 = 3.32$) for HPRS lines 1 and 2 respectively. The results for the two lines were consistent, and taken together the protective effect was significant at the 5% level.

The protective effect of inactivated preparations of productively infected cells, such as received by group E, is directed against virus replication or spread, as shown before^{10,11}. It is unlikely that the protection afforded by the treated lymphoblastoid cell lines was due to the viral antigens which are expressed on the small proportion of the cells which are productively infected, as the number of such cells received by group D was much less than was received by groups A and B (32- and 4-fold, respectively), which were not protected. The protective effect was probably due to the tumour specific antigens present on the cells of the lymphoblastoid cell lines. The failure of tumour cells and lymphocytes from infected chickens to protect may have been a dose effect. Malignant cells form only a minority of the cells of MD lymphomas, the remainder being inflammatory reactive cells^{4,5}. In contrast, almost 100% of the cells of MD lymphoblastoid lines carry tumour specific antigens^{4,5}. Alternatively, the tumour specific antigens present

Table 1 Immunisation schedules

Group	No. of birds*	Inoculum cell type	Age of recipients (d)		
			9	24	42
A	20	Tumour cells	21.4 × 10 ⁶ †	20.8 × 10 ⁶	80.6 × 10 ⁶
B	21	Infected lymphocytes	82.8 × 10 ⁶	76.0 × 10 ⁶	75.0 × 10 ⁶
C	24	Normal lymphocytes	94.8 × 10 ⁶	—	83.1 × 10 ⁶
D	23	Lymphoblastoid cell line cells	15.9 × 10 ⁶	—	26.2 × 10 ⁶
E	19	Infected CKCs	10 ^{3.2} PFU	—	10 ^{4.4} PFU
F	24	None	—	—	—
G	22	HVT (cell free)	10 ^{3.4} PFU	—	—

Tumour cells were freshly explanted cells of ovarian lymphomas from chickens experimentally infected with MDV (HPRS 16 strain). Infected lymphocytes were peripheral blood lymphocytes from the same birds. Normal lymphocytes were peripheral blood lymphocytes from unexposed chickens of the same age. Lymphoblastoid cell line cells were cells of HPRS lines 1 and 2, derived originally from MD lymphomas. Because of difficulties in obtaining large quantities of these cells, 13 birds were inoculated with HPRS line 1 and 10 with line 2. In view of the similarities between the two cell lines¹², these birds were treated as a single group. Infected CKCs were chicken kidney cells infected *in vitro* with HPRS 16 strain of MDV. All cells were assayed for infectivity on CKC monolayers before inactivation by incubation at 20 °C and at a concentration of 10⁸ ml⁻¹ for 15 min in 0.125% glutaraldehyde in phosphate buffered saline (PBS). After inactivation the cells were washed three times in PBS. HVT (cell free) was lyophilised herpesvirus of turkeys (strain FC 126). With the exception of group G, birds received the first inoculum in Freund's complete adjuvant, and subsequently without adjuvant.

* Birds dying of causes other than MD were removed from final group size.

† Quantities shown are doses per bird.

Fig. 1 Cumulative percentage of MD mortality of immunised and control chickens. Group treatments were as detailed in Table 1.

on lymphoma cells may differ from those on the lymphoblastoid cells of the cell lines, perhaps because of reaction with antibody or sensitised lymphocytes *in vivo*.

It has been suggested⁹ that resistance to MD proceeds by a two-step mechanism. The restriction of virulent virus infection brought about by vaccination may result in a much reduced incidence of malignant transformation of T lymphocytes, by reducing the probability of appropriate virus-cell interactions leading to neoplastic transformation. These transformed cells are the targets for the second step, the rejection of neoplastic cells. The immunosuppression caused by the multiplication of virus in the lymphoid organs may also exert an important influence on the outcome of infection. It is known from vaccination studies² and from experimental protection trials using inactivated virus preparations^{10,11} that immunity directed against virus specific antigens is protective. Vaccination, however, does not prevent superinfection with virulent strains of MDV, and the possibility of malignant clones arising still exists. These may be rejected by lymphocytes sensitised against tumour specific antigens. The results of our experiment show that resistance to MD may be induced with tumour specific antigens. The protective mechanism operating in birds which are resistant by virtue of vaccination, genetic composition or age may involve both these components. The nature of the tumour specific antigens and the role played by MDV in inducing their appearance remain unknown.

I thank Miss Brenda Parish for technical assistance, Drs L. N. Payne and B. W. Calnek for helpful discussion, Mr J. Rowell for advice on statistical analysis and Miss Helen Brandon for secretarial assistance.

Isolation of 14-nm virus-like particles from mouse brain infected with scrapie agent

SCRAPIE, a naturally occurring slow virus disease of sheep and goats, has been transmitted experimentally to the mouse, rat, gerbil, mink, hamster, vole and monkey¹. The agent has shown an unusual resistance to ultraviolet irradiation², nucleases³ and β -propiolactone⁴. The precise nature of the scrapie agent, however, has yet to be defined. It is not known whether it is a virus, some type of self-replicating cell membrane, or part of a membrane⁵. The viroid hypothesis of the scrapie agent of Diener⁶ has been discounted^{7,8}. Several different particles have been seen in thin sections of naturally and experimentally infected scrapie tissues⁹⁻¹¹. As repeated fluorocarbon extractions of mink tissues infected with Aleutian disease virus (ADV), which causes persistent infection of mink, have resulted in isolation of the virus^{12,13}, we thought it worthwhile to apply the same physico-chemical techniques in an attempt to isolate virus from mouse brains infected with scrapie agent.

The Chandler or Compton strain of mouse-adapted scrapie was obtained from Dr W. J. Hadlow¹⁴ (Rocky Mountain Laboratory, National Institute of Allergy and Infectious Diseases). Four hundred, 3-week-old female Swiss albino mice of the Animal Diseases Research Institute (Western) stock were inoculated intercerebrally with 0.03 ml of a 10^{-2} mouse brain suspension of the scrapie agent. Eighteen weeks after inoculation, clinical signs of scrapie appeared in many mice and the clinical disease progressed with time. During week 20 after infection some sick mice died. Starting in the week 20 after infection, brains were collected from severely affected mice or from dead mice. At 158 d after infection, all remaining mice were killed and their brains collected. Scrapie brains (132 g in total) were homogenised in 660 ml of saline using an omni-mixer at 15,000 r.p.m. for 15 min. Two parts of the homogenate were added to one part of Freon 113 (DuPont, trichlorotrifluoroethane, $\text{CCl}_2\text{F}-\text{CClF}_2$) and homogenised for 2 min at the same speed. After centrifugation of the Freon homogenate at 10,000g for 30 min, the supernatant was collected. The tissue phase was homogenised in saline and Freon extraction was repeated. Both supernatants were concentrated at 100,500g for 5 h. The ultracentrifuge supernatants were discarded and the pellets were collected. The pellets were suspended in 100 ml of saline, and Freon extraction and concentration of the supernatant were repeated. The final pellets were homogenised in 10 ml of 0.05 M Tris-HCl, pH 7.4, and labelled 'scrapie extract'. This scrapie extract contained protein (0.88 mg ml^{-1}) determined by the micro-Kjeldahl method. A 3.5-ml volume of CsCl solution (14.4 g of CsCl was added to 23.4 ml of 0.05 M Tris, pH 7.4) was put in a centrifuge tube and 1 ml of the scrapie extract was mixed with the top part of the CsCl solution. This was ultracentrifuged at 243,000g for 72 h using a Beckman swing bucket 50.1 Ti rotor. After ultracentrifugation, 10 equal fractions, each approximately 0.45 ml, were collected from the top of the tube using Pasteur pipettes. The pellet deposited in the bottom of the tube was also suspended in 0.45 ml of the Tris (fraction 11).

Two bands were visible in the CsCl gradient, one in fraction 5 and the other in fraction 7. Fractions 9, 10 and 11 were brownish in colour and appeared to contain ferritins. The buoyant

Table 1 Absorbance and electron microscopy of CsCl fractions of scrapie-infected mouse brain extract

Fraction No.	Absorbance		EM
	260 nm	280 nm	
1	0.255	0.191	No 14-nm particles
2	0.347	0.260	No 14-nm particles
3	2.561	2.376	No 14-nm particles
4	0.733	0.677	No 14-nm particles
5	2 × 2.644	2 × 2.597	No 14-nm particles
6	2.480	2.111	Some 14-nm particles
7	2.718	2.026	Numerous 14-nm particles
8	2.039	1.495	Some 14-nm particles and ferritin
9	4 × 2.034	4 × 1.178	Ferritin
10	8 × 2.530	8 × 1.309	Ferritin
11 (Pellets)	Not done		Ferritin

* Diluted with an equal amount of 0.05 M Tris.

densities of these two bands were determined from their refractive indices. The absorbance (A) of each fraction was read at 260 and 280 nm (Table 1). Then 4 ml Tris was added to each fraction and concentrated at 243,000g for 4 h. After ultracentrifugation, the supernatants were discarded and the pellets were resuspended in 0.4 ml of the Tris. For electron microscopy, a drop of each fraction was placed on to a Formvar membrane floating on cold distilled water and dialysed for 1 h. After this, one drop of the dialysed materials was placed on to a 400-mesh carbon coated grid, and allowed to deposit on the membrane of the grid for 3 min. The liquid on the grid was removed with a filter paper. Finally, the grid was stained with 2% potassium phosphotungstate, pH 7.2, and examined with an electron microscope (Hitachi model HU-12A).

Numerous virus-like particles, measuring about 14 nm in diameter, were observed in fraction 7 and lesser amounts were observed in fractions 6 and 8 (Fig. 1). The particles seemed to be spherical. Many were intact, but some seemed to be empty or incomplete. Fractions 8, 9, 10 and 11 contained ferritins¹³. No virus-like particles could be detected in fractions 1–5. These virus-like particles observed in the band in fraction 7 have a buoyant density 1.341–1.350 g cm⁻³, whereas the band observed in fraction 5 has a density of 1.296–1.305 g cm⁻³ in CsCl.

Similar extracts with 5-week-old normal mice brains from the same mouse colony yielded only one visible band in fraction 5, with a buoyant density of 1.296–1.305 g cm⁻³ in CsCl. No band was observed in fraction 7 from normal mice brain extracts. Electron microscopy of fraction 5 of the normal mice brain extracts did not reveal any particles. In the pool of fractions 6 to 8 some ferritin appeared, but no particles comparable with those seen in the scrapie infected mouse extracts.

Fig. 1 14-nm virus-like particles isolated from mouse brains infected with Chandler strain of scrapie agent ($\times 408,000$). Negatively stained with 2% potassium phosphotungstate, pH 7.2.

As known virus control, ADV was ultracentrifuged in the CsCl in the same run as a scrapie extract. The ADV was banded at a buoyant density of 1.405–1.416 g cm⁻³ which is typical of the parvovirus^{13,15}.

If the 14-nm particles isolated from scrapie-infected mouse brain are indeed a virus, they represent the smallest one ever reported. This size corresponds to the theoretical smallest size limit for a spherical virus¹⁶. It is not known whether these particles are indeed the scrapie agent. All the fractions shown in Table 1 are being tested by inoculation of mice to determine the amount of scrapie infectivity in each of them.

Latent infection of the peripheral ANS with herpes simplex virus

In both experimentally infected animals^{1,2} and in asymptomatic human subjects^{3,4} herpes simplex virus (HSV) can establish a latent infection in the sensory ganglia of the nervous system. It is probably the periodic reactivation of virus within these ganglia that gives rise to recurrent herpetic eruptions on

Fig. 1 Acute and latent HSV infection of the SCG after unilateral inoculation into the anterior chamber of the eye. *a*, Time course of SCG infection with HSV: the percentage of ipsilateral ganglia positive for virus by homogenisation (●) and explantation (▲) at various intervals after unilateral anterior chamber inoculation. *b*, Comparison of homogenates of ganglia ipsilateral and contralateral to the side of injection: homogenisation of ganglia at various times after unilateral anterior chamber injection presented both as the percentage of ipsilateral (●) and contralateral (○) ganglia positive for HSV and as the mean number of PFU per positive ipsilateral (●) and contralateral (○) ganglion. *c*, Comparison of explants of ganglia ipsilateral and contralateral to the side of injection: the percentage of ipsilateral (▲) and contralateral (△) ganglia positive for virus at various times after unilateral HSV injection of the anterior chamber. In all experiments the SCG of at least ten mice were assayed at each interval.

epithelial surfaces innervated by the infected ganglia. The ganglia of the peripheral autonomic nervous system seem to share a common embryogenesis with sensory ganglia⁵. Although it has been shown that acute infection of autonomic ganglia with HSV⁶ and the related herpesvirus, pseudorabies virus⁷⁻⁹, can occur, it has not been established that the peripheral autonomic nervous system (ANS) can support a latent infection with these or other viruses. We report here a murine model of latent infection of the superior cervical ganglion (SCG) of the sympathetic division of the ANS.

Four to six-week-old female BALB/c mice (Jackson Labora-

tories) were used. HSV (CHR-3 strain of type 1) was prepared and assayed on primary rabbit kidney (PRK) cells as described previously¹⁰. The SCG, which is situated near the bifurcation of the common carotid artery, was removed under a dissecting microscope in sterile conditions, washed three times in phosphate-buffered saline (PBS) containing antibiotics and assayed for the presence of HSV either by homogenisation or explantation; both carried out (with cocultivation on PRK monolayers) as described for sensory ganglia². Viral titres, expressed as the number of plaque-forming units (PFU) per ganglion, were determined on all homogenates positive for HSV.

The dilator muscle of the pupil is innervated by a rich network of adrenergic nerve terminals which have their cell bodies in the ipsilateral SCG¹¹. To expose these nerves to virus, 8×10^6 PFU of HSV suspended in 4 μ l were injected unilaterally into the anterior chamber of the eye using a 100- μ l syringe and repeating dispenser (Hamilton Co., Reno, Nevada); at various intervals thereafter the ipsilateral SCG was removed and assayed for virus. The data in Fig. 1*a* show that during the acute phase of infection, HSV was detected both in homogenates and explants of the SCG with maximum recovery of virus on days 5 and 6. The acute phase of infection ended at about day 8. Thereafter, homogenates were no longer positive, but HSV could still be recovered by explantation, indicating that the ganglia continued to harbour the virus.

To study the route of viral spread further, both ipsilateral and contralateral ganglia were assayed after unilateral inoculation of HSV into the anterior chamber of the eye. Comparison of bilateral homogenates (Fig. 1*b*) revealed that the amount of virus recovered from ganglia contralateral to the side of inoculation was less than 1% of that recovered from ipsilateral ganglia. Moreover, the occurrence of virus in explants of contralateral ganglia was delayed by 48–72 h compared with ipsilateral ganglia, in which virus could be detected as early as 24 h after inoculation (Fig. 1*c*). These studies indicate a direct, presumably neural, route of viral spread to the ipsilateral SCG. In contrast, spread to the contralateral SCG may involve an intermediary focus of infection (for example, pineal gland or brain parenchyma) although bilateral innervation of the iris or haematogenous viral spread cannot be ruled out.

Corneal inoculation with HSV (Table 1) led to a latent infection of the ipsilateral, but not contralateral, SCG (experiment A). The data from experiments B and C in Table 1 show that virus persisted in the autonomic ganglia for prolonged periods, lasting well over 1 yr. Since mice in experiments B and C were not tested earlier, the differences in the percentage of animals infected at 439 d compared with 114 d cannot be taken as indicating a decline in the prevalence of latent infection with time; assay of the trigeminal ganglia of animals in group C revealed a low prevalence of infection, suggesting a poor initial infection in this group.

The data in Table 2 show the effect of immunisation on the development of latent SCG infection. Mice were first immunised by intraperitoneal injection of HSV; 2 weeks later, when the mean serum neutralisation titre against HSV was 16, the animals were challenged with different doses of virus by anterior chamber inoculation. Mice were killed during the acute and chronic stages of infection, and the ipsilateral SCG was assayed for virus. High mortality and a latent infection of the SCG developed in unimmunised animals with a viral inoculum as low as 8×10^3 PFU. Immunisation prevented mortality and reduced by 80–100% the number of animals developing an infection of the SCG.

The events leading to HSV infection of the SCG can now be described. After anterior chamber inoculation, the virus probably contacts the abundant sympathetic fibres innervating the iris and passes by the neural route to the ipsilateral SCG. After corneal inoculation, either these same nerve fibres or those supplying the neighbouring blood vessels or lacrimal and nasopharyngeal glands serve as the point of viral entry leading to infection of the ipsilateral ganglion. The rapid development of HSV in the SCG supports the argument that virus can travel

Table 1 Latent infection of the superior cervical ganglion with HSV after corneal inoculation

Experiment	Side of assayed ganglion	Days after inoculation	Assay of ganglion by explantation Superior cervical	Trigeminal
A	Ipsilateral	4	11/19 (58%)	9/9 (100%)
	Ipsilateral	26	6/17 (35%)	7/9 (78%)
	Contralateral	26	0/16 (0%)	ND
B	Ipsilateral	114	17/39 (44%)	10/10 (100%)
C	Ipsilateral	439	7/42 (17%)	4/18 (22%)

Mice were inoculated with HSV by corneal scarification, and at different times thereafter the SCG and trigeminal ganglia were assayed for virus by explantation. Results are expressed as the ratio of the number of ganglia positive for HSV to the number of ganglia tested. Mice in experiment A were inoculated unilaterally using a virus pool containing 2×10^8 PFU ml⁻¹. Mice in experiments B and C were inoculated bilaterally with virus pools containing 1×10^8 and 1×10^7 PFU ml⁻¹ respectively. In these latter experiments the results of both the right and left ganglia were combined; thus the number of animals tested in experiments B and C is equal to half of the number of ganglia recorded.

ND, Not done.

Table 2 Effect of immunisation on the acquisition of latent superior cervical ganglion infection with HSV after inoculation into the anterior chamber of the eye

Group	Virus challenge (PFU)	Deaths	Days after inoculation		
			6 (Homogenates)	6 (Explants)	21 (Explants)
Unimmunised	8×10^6	11/30	8/10	10/10	15/19
	8×10^5	18/30	6/10	10/10	10/12
	8×10^4	8/30	5/10	8/10	8/21
	8×10^3	14/30	3/10	8/10	6/15
Immunised	8×10^6	0/15	0/7	1/8	3/15
	8×10^5	0/15	1/8	1/8	0/15
	8×10^4	0/15	0/9	0/8	0/15
	8×10^3	0/15	0/8	0/8	1/15
	None			0/15	0/15

Mice were divided into two groups; one group received a single 0.1 ml intraperitoneal injection of live HSV containing 2×10^6 PFU ml⁻¹, while the other group was not immunised. Two weeks later the animals were further subdivided and challenged with different doses of HSV by the anterior chamber route. Ipsilateral ganglia of mice killed at 6 d after challenge were assayed both by homogenisation and explantation, while ganglia obtained 21 d after challenge, were assayed by explantation alone. Results are expressed as the ratio of the number of ganglia positive for HSV to the number of ganglia tested. Deaths occurred between 7 and 10 d after anterior chamber inoculation and were tabulated at 21 d; the mice killed at 6 d were randomly selected and omitted from computation of mortality.

by direct retrograde axonal transport¹². Once the virus reaches the ganglion, productive viral replication ensues, as indicated by rising viral titres in homogenates. Fluorescent antibody studies reveal that 5 d after inoculation more than half of the neurones in the SCG contain viral antigens (unpublished). At 8 d after inoculation, the SCG homogenates become negative and HSV antigen can no longer be detected by immunofluorescence. Nonetheless, the infection persists, and virus can be recovered by explantation for at least 14 months.

In spite of differences in the organisation and functional roles of the autonomic and sensory ganglia, it seems that both types can support a latent HSV infection. Whether either type of ganglion actually becomes infected probably depends on whether their respective nerve endings are exposed to an adequate concentration of virus. Likewise, whether immunisation can prevent infection may well depend on the availability of anti-viral antibody and/or immune cells at the point where virus makes contact with nerve endings¹³. Our study shows that immunisation is quite effective in reducing the incidence of SCG infection after anterior chamber inoculation.

HSV infection of the SCG promises to be a useful animal model for the study of latent viral infection of the ANS. Moreover, this study raises the possibility that latent infection of autonomic ganglia with HSV or other viruses may well take place in man and could be responsible for periodic or prolonged dysfunction of target organs innervated by these ganglia.

Interval coding of temperature by CNS neurones in thermoregulation

MODELS describing the central nervous control of thermoregulation^{1,2} are based at present on the discharge characteristics of temperature rate-sensitive neurones in the preoptic (PO) area and the hypothalamus. These neurones are believed to be involved in thermoregulation because they are anatomically located in an area affecting thermoregulatory control³⁻⁵ and respond to both local⁶⁻⁸ and peripheral⁹⁻¹¹ temperature change. Examination of the temporal distribution of interspike intervals from PO neurones in our experiments suggests that temperature rate-insensitive PO neurones also process thermoregulatory information.

We used adult New Zealand White rabbits, *Oryctolagus*

cuniculus in our experiments. Several probes were stereotactically implanted¹² in the brain: a thermocouple re-entrant tube in the left lateral PO, a thermode¹³ and a thermocouple re-entrant tube in the lateral border of the right PO and a moveable recording electrode array¹⁴ in the right medial PO equidistant from the thermode and re-entrant tube. The recording electrodes were prepared from 25 μ m diameter platinum-iridium wire. Extracellular potentials were first conditioned by a field effect transistor¹⁵, mounted on the head of the animals, and then amplified and filtered through routine bioelectric equipment. Discharges were typically from single neurones. Neural activity, as well as ambient, ear, brain and PO temperatures were recorded on magnetic tape for subsequent analysis. Neural activity was analysed by a PDP 8-I laboratory computer and represented in the form of mean firing rate and interspike interval (ISI) histograms. The ISI histogram is a plot of the distribution of time intervals between successive neural discharges.

After surgery, the rabbits were allowed to recover for at least 1 week. During experimental sessions, they were placed in a controlled ambient temperature chamber and were not anaesthetised or restrained. After obtaining a unit with a suitable signal-to-noise ratio, control unit activity was recorded for comparison with data collected at hot or cool clamped PO and ambient temperatures.

The experimental ISI histograms were compared statistically with their respective control histogram using χ^2 analysis and the F test. In each case, the experimental values were significantly different ($P < 0.01$) from the control; also, histograms generated at normal PO temperatures after each episode of heating or cooling did not differ significantly from their control histogram ($P > 0.05$).

Figure 1 shows ISI histograms for data from rate-insensitive neurone 2-E7 at an ambient temperature of 22 °C. Although the firing rate did not change significantly ($Q_{10}=1.02$), there was a significant change in the distribution of intervals during PO cooling. Clamping the PO temperature at 35.8 °C resulted in a bimodal distribution of intervals.

The ISI histograms in Fig. 2 indicate that some rate-insensitive neurones respond to both local cooling and heating with a change in interval distribution. These data from rate-insensitive neurone 11-E2 were obtained at 24 °C ambient temperature. At normal PO temperature, the

Fig. 1 Comparison of ISI histograms for rate-insensitive neurone 2-E7. *a*, Control; *b*, preoptic cooling. Each histogram represents 50 s of neural activity. The total number of occurrences of each interval width is expressed on the ordinate. Resolution of the interval width is 2 ms. t_{PO} , Preoptic temperature; t_A , ambient temperature; FR, firing rate (impulses $s^{-1} \pm s.e$)

intervals were distributed unimodally, but during PO cooling or heating ($Q_{10}=0.6$ and 1.4 respectively), the intervals were distributed bimodally. In each case, the bimodal distribution resulted from the increased frequency of short intervals.

Since integrative thermoregulatory neurones receive information concerning external as well as internal temperature conditions, the ISI histograms were examined during ambient thermal stimulation. Figure 3 shows data from rate-insensitive neurone 17-L3 ($Q_{10}=0.9$). The interval distribution by this neurone is similarly by either PO or ambient thermal stimulation. The resulting bimodal distribution resembles that in Fig. 2 and was again a result of the increased frequency of short intervals. This type of neurone integrates thermal inputs from central and peripheral loci as expressed by its ISI distribution.

Fig. 3 Effects of ambient thermal stimulation on the interval distribution of rate-insensitive neurone 17-L3. *a*, Control; *b*, preoptic cooling; *c*, ambient cooling. Histogram details and definitions as in Fig. 1.

Models of the thermoregulatory system should include consideration of the importance of the ISI as a means of coding thermal information. In general the ISI histograms for these and other PO rate-insensitive neurones we have studied change significantly during thermal stimulation. Earlier studies^{16,17} indicated that only a small fraction (30%) of neurones in the PO are thermosensitive and considered to be involved with temperature regulation, however, firing rate was the only parameter used to determine

thermosensitivity and in addition, they dealt with anaesthetised animals. Consequently, our study may not conform to earlier results because our animals were capable of thermoregulation and not anaesthetised.

Evoked transmitter release increased by inorganic mercury at frog neuromuscular junction

It is well documented that calcium ions have an important role in the release of transmitter substances from nerve terminals^{1,2}. There is, however, little information about the interactions of calcium with other chemical moieties within the nerve terminal which presumably are required to bring about transmitter release. Kosower and Werman³ postulated that calcium ions interact with two sulphhydryl groups to form a calcium dithiolate complex. The formation of such a complex results in a decrease in the sulphur-sulphur distance which is presumed to produce a microcontraction of the presynaptic membrane, thereby allowing for the quantal release of transmitter into the synaptic cleft. We show here that low concentrations of mercury ions (1 μ M or less) increase the amount of transmitter released from motor nerve terminals. Since it is well known that mercury ions dissociating from inorganic mercury (HgCl_2) form disulphide bridges in the presence of sulphhydryl groups, we interpret our observations as being consistent with Kosower and Werman's hypothesis.

Experiments were performed *in vitro* on frog (*Rana pipiens*) sciatic nerve-sartorius muscle preparations maintained in a suitable chamber. Superficial neuromuscular junctions were viewed through a compound microscope with a total magnification of $\times 400$. Subthreshold endplate potentials (e.p.p.s) were produced by bathing the preparations in high magnesium/low calcium Ringer solution. The composition of the control Ringer solution was: 111 mM NaCl, 2.5 mM KCl, 0.36 mM CaCl_2 , 1.1 mM MgCl_2 , 4 mM Tris-maleate. Micromolar amounts of HgCl_2 were added to this Ringer solution to test for both presynaptic and postsynaptic effects of mercury ions. All Ringer solutions were maintained at pH 6.9 and 15 °C. Microelectrodes filled with 1 M potassium citrate were used for intracellular voltage measurements. A signal averager (Computer of Average Transients 1000) was used to record the mean e.p.p. To determine whether changes in the e.p.p. were

due to a direct effect of mercury ions on the postsynaptic receptors, these receptors were activated directly through the iontophoresis of acetylcholine (ACh) from a micropipette rather than indirectly by nerve stimulation, which results in the neural release of ACh.

Figure 1 shows that mercury had an intense potentiating effect on the e.p.p. amplitude. In this experiment, the mean e.p.p. amplitude was recorded during prolonged exposure of the preparation to 1.0 μ M Hg^{2+} . The e.p.p. increased from a control level of 1.4 mV to a value near 7.3 mV within 30–40 min of the beginning of the mercury exposure. The addition of 0.1 μ M Hg^{2+} a few minutes before the addition of the 1.0 μ M Hg^{2+} resulted in no detectable change in the e.p.p. amplitude. The percentage increase from control after addition of 1.0 μ M Hg^{2+} was 420%. The e.p.p. amplitude did not remain steady at this value of 7.3 mV, but it soon began to fall, eventually to zero. The increase in e.p.p. amplitude brought about by Hg^{2+} is very similar to the effect of diamide on the e.p.p. observed by Werman *et al.*⁴. These investigators suggest that diamide increases the e.p.p. amplitude by the formation of disulphide bonds in the presynaptic nerve terminal, which, according to their hypothesis, results in an increased quantal release of transmitter.

The potentiating effect of mercury ions on the e.p.p. occurs when mercury is present in low concentrations—either 1.0 μ M or less. In one experiment, 0.01 μ M mercury increased the e.p.p. by 33%; in another, 0.1 μ M mercury increased the e.p.p. by 26%. In the latter experiment, washing the preparation with mercury-free Ringer solution resulted in only a slight fall of the e.p.p. towards the control

Fig. 1 Effect of the e.p.p. of a prolonged exposure to 1.0 μ M HgCl_2 . The amplitude of the mean e.p.p. is plotted on the ordinate against time. Each point represents the mean of 100 e.p.p.s. E.p.p.s were recorded by conventional intracellular microelectrode techniques, and neuromuscular blockade was produced by bathing the preparation in high magnesium/low calcium Ringer solution. During the averaging of the e.p.p., the motor nerve was stimulated at a rate of two per s. 0.1 μ M HgCl_2 caused no detectable change in the e.p.p. amplitude; however, the addition of 1.0 μ M HgCl_2 increased the e.p.p. amplitude by 420% from the control value. The e.p.p. amplitude did not remain constant during the prolonged exposure to 1.0 μ M mercury ions; after reaching its peak amplitude, the e.p.p. amplitude eventually fell to zero. The concentration of Ca^{2+} was 0.36 mM and of Mg^{2+} , 1.1 mM. The temperature was 15 °C.

Fig. 2 Lack of a postsynaptic effect of HgCl_2 . ACh was iontophoretically applied to the endplate receptors. The amplitude of the ACh potential was plotted on the ordinate against time. The oscillogram in *a* shows the control ACh potential (upper trace) and the corresponding iontophoretic current in the lower trace. Records in *b* and *c* show that, respectively, 1.0 and 10.0 μM HgCl_2 had no obvious effect on the amplitude of the ACh potential. Each point on the plot represents the amplitude of a single ACh potential. Note the presence of a single m.e.p.p. on the falling phase of the ACh potential in *c*; 10.0 μM HgCl_2 , as in other experiments, increased the m.e.p.p. frequency. The concentration of Ca^{2+} was 0.36 mM and of Mg^{2+} , 1.1 mM. The temperature was 15 °C.

value, illustrating our consistent finding that this effect of mercury is irreversible. When this same preparation was exposed to 10.0 μM mercury, the e.p.p. at first increased further, then decreased quickly to zero.

del Castillo *et al.*⁵⁻⁷ have shown that several types of sulphhydryl reagents including oxidising agents, organic mercurials and divalent mercury ions depolarise the endplate membrane. They suggest that activation of the endplate involves a change in certain membrane sulphhydryl groups from their initial reduced form, a process essentially identical to that proposed for presynaptic transmitter release by Kosower and Werman (see ref. 3). To determine whether the effects of HgCl_2 on the e.p.p. amplitude in our experiments were presynaptic or postsynaptic in origin, the amplitude of the iontophoretic potential (ACh potential) produced by a constant amount of ACh released from a micropipette was observed before and during exposure of the preparation to HgCl_2 . Identical Ringer solutions were used during the control periods of the experiments illustrated in Figs 1 and 2.

Figure 2 contains a plot of the amplitude of the ACh potential (ordinate) against time; measurements of the amplitude were obtained before and after the application of 1.0 μM and 10.0 μM mercury ions. Figure 2*a*, *b* and *c* are representative oscillograms of these ACh potentials. The ACh pipette was highly localised at the intrinsic receptors⁸; the ACh sensitivity⁹ was quite high, the value being 787 mV nC⁻¹ for the recording made during the control period (Fig. 2*a*). Mercury caused no great increase in the amplitude of the ACh potential; the ACh potential measured in 10.0 μM mercury (Fig. 2*c*) was 4.2% higher than that measured during the control period (Fig. 2*a*). Clearly then, the massive increase in the e.p.p. amplitude observed in the experiment of Fig. 1 was due to a presynaptic effect of mercury ions.

We conclude that 1.0 μM mercury increased the amount of transmitter released from the nerve terminal after the arrival of an action potential, and that the large increase in the e.p.p. amplitude was due principally to this potentiating effect of the low concentration of mercury on evoked transmitter release. These experiments suggest that sulphhydryl groups are involved in the release of transmitter from nerve terminals. We suggest that, at very low con-

centrations of HgCl_2 , mercury dithiolate bridges form within the presynaptic nerve terminal as the presynaptic action potential arrives. In these conditions, mercury ions are presumed to act like calcium ions with regard to the evoked release of transmitter. But as the concentration of mercury ions is increased or the exposure time to a relatively low concentration of mercury ions is increased, transmitter release is blocked, presumably because the bonds between sulphur and mercury are relatively irreversible and do not allow for thiol groups to be reformed as they would in the presence of calcium ions.

The frequency of miniature endplate potentials (m.e.p.p.s) was unaffected by mercury concentrations of 1.0 μM or lower. Only at concentrations of 10 μM or more—concentrations at which the e.p.p. was usually blocked completely—did we observe an increase in m.e.p.p. frequency. Methyl mercury chloride has also been observed to produce an increase in m.e.p.p. frequency as well as neuromuscular blockade¹⁰. Thus, the action of mercury ions on the evoked release of transmitter occurs at much lower concentrations than its effects on spontaneous release. This is similar to the effects of PbCl_2 on the neuromuscular junction¹¹ except that low concentrations of PbCl_2 only decreased the e.p.p., never increased it.

It is uncertain what direct bearing the results of these experiments may have on neuromuscular disorders associated with chronic mercury poisoning. It is interesting, however, that a study¹² of methyl mercury poisoning showed that patients benefit from the administration of neostigmine, an anticholinesterase agent. Thus, although other interpretations are possible, it may be that disturbances in the release of acetylcholine from motor nerve terminals may prevail in chronic mercury poisoning.

Effect of internal fluoride and phosphate on membrane currents during intracellular dialysis of nerve cells

It has become possible recently to isolate single neurones from molluscan ganglia by the use of proteolytic enzymes, so that the external solution can be changed easily^{1,2}. One advantage is that the absence of the axon makes the application of the voltage clamp technique to isolated neurones more effective³. We describe here a further development—an attempt to produce wide ranging changes in the ionic com-

Fig. 1 Experimental design for intracellular dialysis and voltage clamping. The dimensions of the pore were: $D_1 = 200 \mu\text{m}$, $D_2 = 40 \mu\text{m}$. Polyethylene film has a thickness d of $400 \mu\text{m}$. The suction in the pore is regulated by changing the level of the outflow as shown by a vertical arrow. Electric circuits: 1, unity gain input amplifier; 2, amplifier for voltage clamping; 3, current-measuring amplifier.

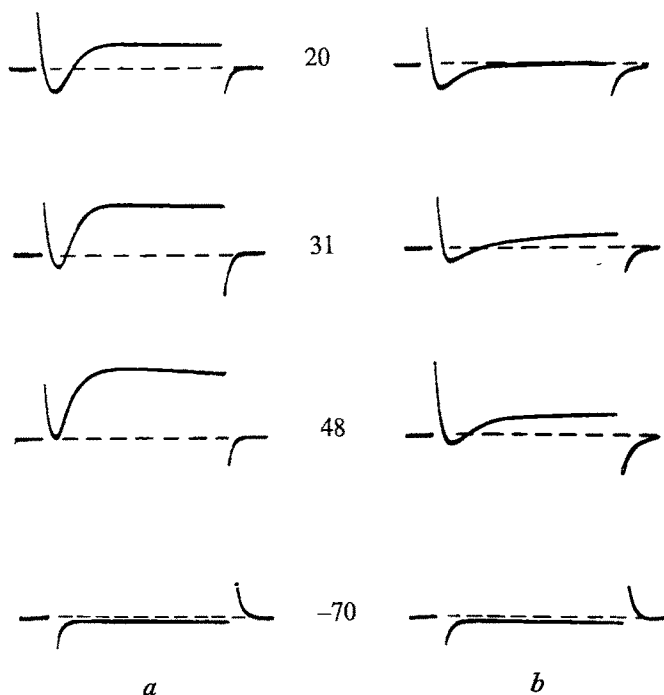

Fig. 2 Effect of a decrease in the internal potassium concentration. Potassium concentration in the lower compartment was decreased from 60 mM (a) to 2 mM (b). Osmolarity was maintained with Tris-HF (pH 7.3). Normal Ringer solution was in the upper compartment. Membrane potentials at test pulses (in mV) are indicated by numbers near the corresponding current traces. Holding potential was -40 mV . Calibrations: $4 \times 10^{-8} \text{ A}$, 10 ms.

position of the intracellular medium of neurones isolated from the snail *Helix pomatia*.

The experimental design is shown in Fig. 1. The perfusion chamber consists of two compartments separated by a polyethylene film with a conical pore. If a small negative hydrostatic pressure is created in the lower compartment, a suction effect is created in the pore. When an isolated cell is transferred to the solution in the upper chamber, it plugs the pore and becomes fixed in it. The walls of the pore are covered with an adhesive material made from Parafilm which helps to reduce leakage between the cell membrane and the walls of the pore. The part of the cell membrane that is exposed to the lower

Fig. 3 Currents and $I-E$ relationship for the peaks of inward current in the cell containing phosphate anions. Solution in the lower compartment: 100 mM Tris- H_2PO_4 , pH 7.3, 20 mM sucrose. Upper compartment: normal Ringer (a, \bullet on the $I-E$ curve); Na-free solution (b, half-closed circles). Leakage was compensated for in this experiment as described in the text. Holding potential was -40 mV . Calibrations: $6 \times 10^{-8} \text{ A}$, 100 ms.

compartment is subjected to the action of calcium-free iso-osmotic (or slightly hypo-osmotic) potassium salt solution, pH 7.3, which is perfused through this compartment; this rapidly destroys the barrier properties of the membrane. (The presence of potassium is not critical in this respect since the absence of calcium itself is usually sufficient.) The upper part of the surface membrane which is in contact with normal Ringer solution (100 mM NaCl, 10 mM CaCl_2 , 2 mM KCl, 10 mM Tris-HCl, pH 7.5) in the upper compartment usually maintains its electrical excitability.

Being fixed in a pore, the cell membrane is electrically controlled with the help of the Ag/AgCl/saturated KCl electrodes connecting the solutions in both compartments to the voltage clamp device as shown in Fig. 1. Resultant membrane potential values of -20 to -30 mV can be recorded between

the two compartments showing that leakage is not more than twice as great as that normally observed in the isolated cells.

On repolarisation to a normal resting potential (-40 to -50 mV), the upper part of the membrane produces either reduced or, in many cases, full sized action potentials.

Thus we were able to dialyse the cell body and so change the intracellular ionic composition. The effectiveness of dialysis was tested first by replacing the potassium in the lower compartment by Tris. This substitution resulted in a quick (1–5 min) and marked decrease in the delayed outward current carried by potassium ions (Fig. 2).

The stability of the membrane depended largely on the kind of anions in the dialysing solution. In 100 mM KCl (or Tris-HCl) the membrane could not maintain its initial condition for sufficient time to facilitate its study. The leakage current grew continuously and the ionic currents deteriorated. NO_3^- was even less favourable in this respect. With fluoride or phosphate salts, however, the membrane showed a remarkable stability which exceeded that found during usual micro-electrode experiments on intact cells. The leakage conductance was stable for hours and did not depend on potential within the range of potential changes used. Thus we could compensate for leakage by adding to the current signal a square pulse proportional to the potential step.

The properties of the inward current were strikingly different

Fig. 4 Currents and I - E relationship for the peak inward current in the cell containing fluoride anions. Lower compartment: 100 mM Tris-HF, pH 7.3, 20 mM sucrose. Upper compartment: normal Ringer (a, \blacksquare); Na-free solution (b, \triangle). Leakage was compensated for. Holding potential was -40 mV. Calibrations: 3×10^{-8} A; 20 ms.

depending on whether fluoride or phosphate anions were introduced into the cell. When dialysed with phosphate salts the cells developed inward currents which were independent of external sodium and carried only by calcium ions. When external sodium was replaced by Tris there was no decrease in the inward current, but a slight increase could be observed, as if there was a degree of potential-dependent blocking of inward current channels by sodium (Fig. 3). In cells containing fluoride, however, the inward membrane current was carried entirely by sodium, disappearing after replacement of this ion (Fig. 4). An increase in external calcium did not abolish this effect. A cell dialysed first in the presence of phosphate salts and demonstrating calcium inward currents could be made to transport sodium by the introduction of fluoride. In neither state were the inward currents sensitive to tetrodotoxin, and the slope conductances of their steady state I - E relationships were similar, indicating that probably the same system of channels is involved in the transfer of either calcium or sodium ions. The change of the inward current channels was not completely reversible: the change back from fluoride to phosphate was followed by a sharp decrease in maximum current.

The calcium current detected in the cells containing phosphate had kinetics different from those of the sodium current in the cells containing fluoride. The latter inactivated completely, the time course being exponential (Fig. 4), whereas the former had a small, very slowly inactivating component (Fig. 3). This component may be similar to a slow calcium current recently observed in unisolated neurones⁴.

The reversal potential for this late component was 20–30 mV less positive than for the early inward current which reversed at about +50 mV (Fig. 3). This could be due to its contamination by a residual small potassium current which could be observed at high depolarisation.

We thank Professors H. Grundfest and H. Meves for helpful discussions.

Simultaneous changes in fluorescence and optical retardation in single muscle fibres during activity

WHEN a skeletal muscle is stimulated to twitch, small changes in the optical properties of the fibres can be detected which may give information about excitation-contraction coupling. An example is provided by the experiments of Bezanilla and Horowicz^{1,2}. After treatment of muscles with Nile Blue A, fluorescence changes were found which, it was suggested, arise from changes in potential across the membranes of the sarcoplasmic reticulum (SR). Such potential changes might reflect the movement of calcium ions from inside the SR into the myoplasm, a step in the normal activation of contraction. Baylor and Oetliker^{3,4} measured changes in optical retardation, which rely on the inherent birefringence of a muscle fibre rather than the addition of an extrinsic probe. The large second component of the signal was suggested to arise from a change in SR membrane potential. These explanations are plausible since small changes in both extrinsic fluorescence

Fig. 1 Tension, Nile Blue A fluorescence and optical retardation in a single muscle fibre during a twitch. Records *a-c* show twitch tension recorded in Ringer (*a*), 18 min after introducing Ringer + Nile Blue A ($0.0002 \text{ mg ml}^{-1}$) (*b*), and 10 min after replacing with 270 mM NaCl Ringer + dye ($0.0002 \text{ mg ml}^{-1}$) to block movement (*c*). The tension recorded in isotonic solution was relatively low since the fibre was small, diameter $56 \mu\text{m}$, and was stretched to 1.55 times slack length. Records *d-f* show optical measurements made after the hypertonic Ringer was introduced. *d*, Change in fluorescence expressed as change in light intensity divided by resting fluorescent light intensity, using light of $570 \pm 30 \text{ nm}$ to illuminate the fibre (determined by primary filter) and measuring light of wavelengths longer than 630 nm (determined by secondary filter). *e*, Fluorescence control expressed as change in light intensity divided by the resting intensity used in *d*, obtained by placing the secondary filter between the primary filter and the fibre. *f*, Change in optical retardation using light of $570 \pm 30 \text{ nm}$. For records *a*, *b* and *f*, 16 traces were signal averaged; for *c*, *d* and *e*, 32 traces were averaged. In each record the fibre was stimulated 10 ms after the beginning of the sweep as indicated by the stimulus artefacts. An upward deflection in the optical traces represents an increase in light intensity, as indicated by the arrows. Temperature, $12-13^\circ\text{C}$.

and optical retardation are known to accompany voltage changes across neuronal membranes⁵⁻⁸. An important test of these hypotheses is to compare the fluorescence and retardation signals from the same fibre, to see if they follow the same time course.

Single fibres from the semitendinosus or ilio-fibularis muscle of English frogs (*Rana temporaria*) were isolated and mounted horizontally in a narrow chamber with glass sides. One tendon end was connected to an RCA 5734 transducer for monitoring tension. The chamber was then placed on an optical bench (Spindler-Hoyer) where the light from a tungsten-halogen source could be focused on the fibre by a long working distance objective ($\times 32$, N.A. 0.60). An identical objective was placed on the opposite side to collect the transmitted and emitted light. Light collected from 0.3 mm of fibre was measured by a photodiode (PV-100, E.G. & G., Inc.). The tension transducer and the photodiode were connected to Tektronix 3A9 amplifiers, bandwidth d.c. to 3 kHz, and the outputs were sampled and

signal averaged on-line by a PDP-8/e computer. Measurements of fluorescence were made using a wide-band interference filter (primary filter) placed between the light source and the muscle fibre and a longer wavelength cut-on filter (secondary filter, Schott R.G. series) placed between the fibre and the photodiode. Optical retardation was measured with two polarisers placed on either side of the fibre, one at -45° and the other at $+45^\circ$ with respect to the fibre axis⁴. A shutter limited the exposure of the fibre to light. For data collection the fibre was stimulated externally with 0.2 ms pulses at a rate of $0.1-0.2 \text{ s}^{-1}$. Only fibres that gave all-or-nothing mechanical and optical responses were used. Optical recording was usually done about 1 mm from the cathod. The Ringer solution contained 120 mM NaCl, 2.5 mM KCl, 1.8 mM CaCl_2 , 2.15 mM Na_2HPO_4 and 0.85 mM NaH_2PO_4 , pH 7.1 (ref. 9). Mechanical movement was sometimes blocked by increasing the NaCl concentration to 270 mM, thus making the tonicity of the solution about 2.2 times normal.

In the first experiments with Nile Blue A it became apparent that single fibres do not survive well in the concentration used successfully on whole muscle^{1,2}, 0.02 mg ml^{-1} . In one experiment a 20-fold dilution produced a potentiation of the twitch of about 50% in 10 min, which was

Fig. 2 Tension, indodicarbocyanine fluorescence and optical retardation during a twitch. Records *a-d* show twitch tension in Ringer (*a*), 14 min after introducing Ringer + 0.002 mg ml^{-1} of the dye (*b*), 13 min after returning to normal Ringer (*c*), and 5 min after replacing with 270 mM NaCl Ringer (*d*). The fibre was in the dye solution for 19 min, then in isotonic Ringer for 14 min before hypertonic Ringer was introduced. Records *e-g* show singlesweeps of changes in fluorescence (*e*), fluorescence control (*f*), and changes in optical retardation (*g*), all made after hypertonic Ringer was added. For fluorescence measurements the primary filter passed light of $570 \pm 30 \text{ nm}$ and the secondary filter passed light of wavelengths longer than 665 nm . Optical retardation was measured using light of $570 \pm 30 \text{ nm}$. Stimulation time indicated by arrows. Fibre diameter $151 \mu\text{m}$; stretched 1.32 times slack length. Temperature $14-16^\circ\text{C}$. The later portion of the optical retardation signal in this experiment is different from that shown in Fig. 1, the reason probably being related to degree of stretch (unpublished results of S.M.B. and H.O.).

reversed within 15 min after removing the dye. Since a 100-fold dilution, $0.0002 \text{ mg ml}^{-1}$, had little or no potentiating effect, this concentration was used for optical recording. Record *a* in Fig. 1 shows tension recorded in Ringer solution, record *b* in Ringer plus dye, and record *c* after 270 mM NaCl Ringer plus dye was introduced to minimise movement artefacts on the optical traces. Signal-averaged records of fluorescence (*d*) and of optical retardation (*f*) were each taken with the fibre in hypertonic solution. The initial phases of both signals are qualitatively similar to the signals observed at normal tonicity, except that hypertonicity reduced the maximum rate of change by a factor of 4 for optical retardation⁴ and about 3 for fluorescence. The change in light intensity in record *d* represents primarily a change in fluorescent light from Nile Blue A since the signal was not seen without the dye and was greatly reduced when the secondary filter was placed between the primary filter and the muscle fibre, record *e* ('control' trace). Similarly, the signal in record *f*, corresponding to Baylor and Oetliker's second component⁴, represents a change in optical retardation since it can be reversed by adding an appropriate amount of compensation (not shown). The conclusion from the experiment is that the fluorescence and optical retardation signals are similar in appearance, at least initially, but that the noise level of the fluorescence traces *d* and *e* is too high to permit accurate quantitative comparison. For this reason, it was desirable to find a fluorescent dye that would give a larger signal, without otherwise affecting the fibre.

A marked improvement in the signal-to-noise ratio was obtained with an indodicarbocyanine dye (dye 122 in ref. 7) which could be used in concentrations up to 0.002 mg ml^{-1} with little effect on the twitch. Record *a* in Fig. 2 shows tension recorded in Ringer; *b*, after introducing the dye; *c*, after returning to Ringer; *d*, after replacing with 270 mM NaCl Ringer. Record *e* shows a single fluorescence trace (that is, not signal averaged), *f* shows a single fluorescence control trace and *g* shows a single optical retardation trace, all taken with the fibre in hypertonic solution. Apart from the slight hump in trace *g*, which occurs just before the downward deflection, traces *e* and *g* are remarkably similar. The cause of the hump, which was seen only when dye was used, is not understood. In this experiment the change from isotonic to hypertonic solution reduced the maximum rate of change of both optical signals by a factor of 6.

Since a merocyanine dye (dye I of ref. 7, available as Merocyanine 540, Eastman Organic Chemicals) has been reported to give a fluorescence signal originating mainly from T-system membrane¹⁰, it was interesting to try this dye as well. Figure 3 shows results from two experiments. *A* shows signal-averaged records obtained in isotonic Ringer plus dye. Trace *a* shows tension, *b* shows fluorescence, and *c* gives the control for fluorescence. Although movement artefacts became apparent once tension started to develop, it is clear that the fluorescence signal was early and transient, unlike the fluorescence signals obtained using the other dyes. In other experiments, the merocyanine signal propagated with a velocity comparable with that expected for an action potential, making it unlikely that it represents some sort of movement artefact. This merocyanine dye is toxic⁷ to single muscle fibres, however. Similar experiments in hypertonic solution were even more difficult to carry out. Figure 3*B* shows our best attempt. Record *a* indicates tension, *b* and *c* show fluorescence and fluorescence control, respectively, and *d* shows optical retardation. It is apparent that the change in fluorescence precedes the large change in optical retardation, a finding consistent with the idea that merocyanine is an indicator of surface and T-system membrane potential.

The general conclusion from these experiments is that the second component of the optical retardation signal and the fluorescence signal from Nile Blue A or an indodicarbo-

cyanine dye have approximately the same time course, making it likely that they are indicators of the same basic process or processes. Since changes in membrane potential can give rise to both types of optical signals, the similarity of the signals might be considered as evidence for such a mechanism in muscle. If so, the arguments of Bezanilla and Horowicz² and Baylor and Oetliker⁴ make the SR membrane the likely candidate. Although this view is attractive,

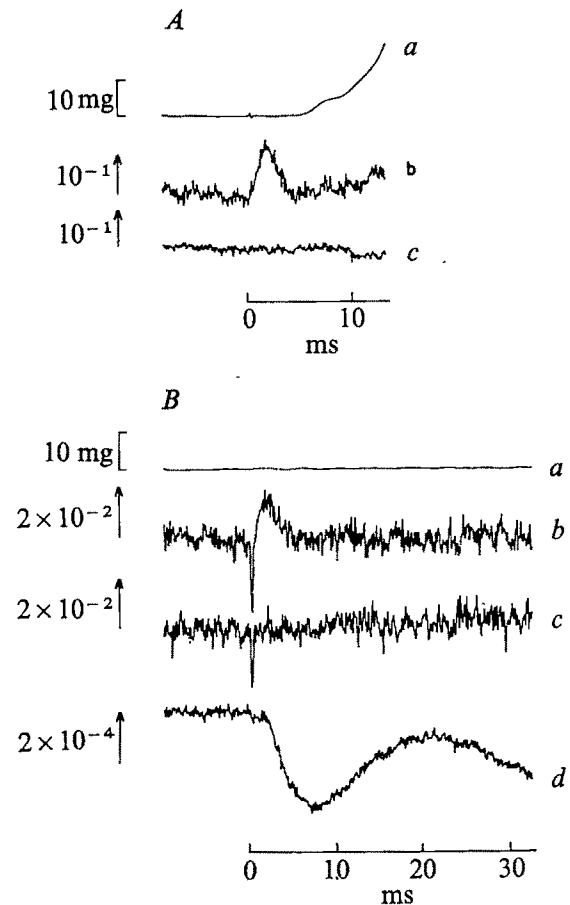

Fig. 3 Tension, fluorescence and optical retardation using a merocyanine dye. *A*, records made in isotonic Ringer saturated with the dye. Trace *a* shows tension, *b* shows change in fluorescence and *c* shows the fluorescence control; four sweeps were signal averaged for *a* and *b*, 16 for *c*. The traces were cut off at the time when large movement artefacts started to develop on the optical traces. Fibre diameter and stretch were not recorded. *B*, records obtained from a different fibre in 270 mM NaCl hypertonic Ringer without dye following 30 min in normal Ringer + dye. The dye in the soaking solution was dissolved in ethanol and Pluronic F-127 (BASF Wyandotte, as described in ref. 7) before being added to Ringer to give a final concentration of 0.018 mg per ml of dye, 0.2% ethanol and 0.02% Pluronic. Just before use the solution was filtered through a 0.22- μm Millipore filter. Trace *a* shows tension, *b* shows fluorescence change, *c* gives the fluorescence control and *d* gives the change in optical retardation using wavelengths longer than 665 nm; eight sweeps were signal averaged for *a*, *b*, *c* and four sweeps were averaged for *d*. Fibre diameter 123 μm ; stretched 1.31 times slack length. For the fluorescence measurements in *A* and *B* the primary filter passed light of $570 \pm 30 \text{ nm}$ and the secondary filter passed wavelengths longer than 630 nm. All solutions were bubbled with N_2 . These experiments were carried out at room temperature, 19°C in *A* and 21°C in *B*.

other explanations should also be considered. For example, optical signals might accompany an increase in myoplasmic calcium or a possible change in SR volume related to calcium release. In any event it is encouraging that fluorescence as well as birefringence methods can be made to work on single muscle fibres without the use of signal

averaging, and that different dyes might be used to follow different steps in muscle activation.

This work was supported by the National Institute of Health. We thank Mr H. Fein and staff for help with design and construction of equipment. We also thank Drs L. B. Cohen, W. N. Ross and B. M. Salzberg for help with the use of dyes and, with Dr R. W. Tsien, for reading the manuscript. A sample of indodicarbocyanine dye was provided by Drs A. S. Waggoner and C. H. Wang.

Membrane noise in slowly adapting stretch receptor neurone of lobster

ANALYSIS of membrane noise in excitable membranes may yield information about the kinetics governing the conductance control of various ionic channels. Such analysis has been applied to noise arising from conductance fluctuations in, for example, the potassium system^{1,2} or the system of postsynaptic ionophores^{3,4}. This report deals with noise that seems to be generated in the sodium channel of the slowly adapting stretch receptor neurone of lobster. We recorded this noise as current noise under voltage clamp, and subsequently analysed it with respect to its covariance and spectral density function. A particularly low degree of Na inactivation at polarisations down to firing threshold was inferred from these analyses.

We used isolated cells mounted in a chamber continuously perfused with solutions of desired composition at 18 °C. For voltage clamp, the same low resistance (5–8 MΩ) micro-electrode, filled with 3 M KCl, was used for measuring the membrane potential and passing the potential controlling currents. This we did by subtracting any potential artefact due to current flow in the electrode from the output signal of the input amplifier before passing it on to the control amplifier. Tests with electronic circuits simulating the membrane and microelectrode showed that a satisfactory signal subtraction of this kind could be achieved for control currents up to 5 nA in a frequency range of 0–250 Hz. After bandpass filtration (cut-off frequencies at 1.6 and 350 Hz), the recorded current noise was processed on a PDP-15 computer for determination of the covariance function and its Fourier transform (spectral density function) between 2 and 400 Hz.

A distinct voltage noise was seen in the slowly adapting stretch receptor neurone of lobster at subthreshold conditions. This noise increased with increasing depolarisation and became indiscernible only after polarisation beyond resting potential. Under voltage clamp the corresponding current noise exhibited a similar polarisation dependence (Fig. 1a and b). The membrane noise was abolished by addition of 120 nM tetrodotoxin or by complete substitution of choline or Tris for extracellular Na⁺ (Fig. 1c and d). The noise was unaffected, however, by 20 mM tetraethyl-

ammonium (Fig. 1e and f), whose ability to block the K channel was manifested by elimination of the after-hyperpolarisation of the action potential. These pharmacological tests show that the Na system was involved in the generation of noise in our preparation.

For a more detailed analysis of the noise generating process, covariance and spectral density functions were computed for current noise recorded at different levels of membrane polarisation. The results of such analyses showed that for more moderate depolarisations the computed covariance and spectral density functions agreed well with theoretical values typical of a first-order noise generating process (Figs 2 and 3). For depolarisation close to firing threshold, however, the computed covariance function deviated in a sinusoidal fashion from an exponential development (Fig. 2), and the spectral density function formed a hump superposed on the simple $[1 + (f^2/f_0^2)]^{-1}$ relationship (Fig. 3). It also seemed that with depolarisation there was an increase in time constant of the covariance function and a decrease in half-power frequency (Fig. 3) of the spectral density function. Finally, the noise variance (that is the covariance function at zero time) increased at an increasing rate with depolarisation.

The more complicated behaviour of the computed covariance and spectral density functions in near-threshold conditions was interpreted to indicate the presence of some periodic signals in the noise. In our preparation such signals could arise in connection with a subthreshold repetitive activity in peripheral cell regions where voltage was not well controlled and will not be considered here.

With regard to the first-order process which seems to underlie noise generation at all lower, but presumably also at higher depolarisations, it is assumed to be identical with the gating process of the Na channel. This gating process can be envisaged as some kind of state transition in channel gating elements, whereby the transition intensity obeys first-order kinetics^{5,6}. Measurements of so-called gating currents have verified the presence of first-order kinetics, at least as far as state transitions in the Na activating system are concerned^{7,8}.

For a more detailed interpretation of our noise recordings we presume that the Na channel is gated by an activating (*m*) and by an inactivating (*h*) system⁹. Provided that both of these systems are subject to random state variations, which is likely from thermodynamic principles, both will generate noise components (henceforth called *m* and *h*-noise

Fig. 1 Membrane current noise recorded at resting potential (–60 mV) (a); at 8 mV depolarisation from resting potential (b); at 8 mV depolarisation in the presence of 120 nM tetrodotoxin (c); at 14 mV depolarisation after substitution of choline for extracellular Na⁺ (d); at 8 mV depolarisation in the absence (e), and in the presence (f) of 20 mM tetraethylammonium. The current calibration represents an approximation.

Fig. 2 Covariance function (ordinate) computed for current noise recorded at resting potential (-70 mV) (\bullet) and at 12 mV (\times), 13 mV (\square), and at 14 mV (\blacksquare) depolarisation from resting potential, and at 16 mV depolarisation in the presence of 120 nM tetrodotoxin (\circ). ---, Theoretical values which are proportional to $\exp(-|\Delta t|/\tau)$, where Δt represents the time lag (abscissa) and τ a time constant whose value varies between 1.6 and 7.9 ms.

components) which then combine in the formation of the membrane noise.

If it is assumed that, in subthreshold conditions, the time constants for state transitions in the m and h system are of the order of 0.1 – 0.3 ms, and 1 – 10 ms, respectively⁹, it follows that the bandwidth of the m noise will extend well beyond 500 – $1,500$ Hz, whereas that of the h noise will stay below 150 Hz. This would mean that in the present recording conditions most of the high frequency m -noise components had no chance of appearing in the noise recordings. In consequence, the computed covariance and spectral

Fig. 3 Spectral density function (ordinate) computed for current noise recorded at resting potential (-70 mV) (\bullet) and at 13 mV (\square), and 14 mV (\blacksquare) depolarisation from resting potential, and at 16 mV depolarisation in the presence of 120 nM tetrodotoxin (\circ). ---, Theoretical values which are proportional to $[1 + (f^2/f_0^2)]^{-1}$, where f represents the frequency (abscissa) and f_0 the half-power frequency whose value varies between 20 and 100 Hz (arrows). The dotted line is fitted by eye.

density function can contain no information regarding the kinetics of the m system. The presence of low frequency m -noise components in the recorded noise may, however, explain the steep increase of the noise variance with increasing depolarisation. With respect to the h -noise, because of its narrow bandwidth it would be expected to pass the filtering circuits of the recording system fairly undistorted and therefore be able to reveal the kinetics of the h system. For this reason it is held that the voltage dependent changes in time constant of the covariance function,

or half-power frequency of the spectral density function are true indications of the voltage dependence of the kinetics of the h system. It is therefore concluded that in our preparation the time constant of the h system is increasing monotonously as the membrane potential is lowered towards firing threshold. This indicates a low degree of Na inactivation in near-threshold conditions. The reason for this could be an especially fast transition from 'closed' to 'open' conformation of the h system, as is occasionally found in particularly non-accommodating nerve fibres^{10,11}.

Functionally, such setting of the Na channel gating system would provide for the occurrence of a subthreshold steady-state Na conductance¹², which might explain the non-adapting mode of firing in our preparation¹³. This hypothesis is corroborated by the fact that a distinct Na noise is not demonstrable in the fast adapting stretch receptor neurone of lobster.

Subthreshold membrane currents in slowly adapting stretch receptor neurone of lobster

In the slowly adapting stretch receptor neurone of lobster, application of tetrodotoxin (TTX) causes a simultaneous hyperpolarisation and decrease in input resistance¹. These effects have been attributed to a possible increase in potassium conductance. They could, however, be explained by elimination of a subthreshold steady-state sodium conductance which, in this case, might underlie the cell's repetitive mode of firing². To examine this possibility, we made a voltage clamp study of the subthreshold steady-state membrane currents of the slowly adapting stretch receptor neurone of lobster. The results indicate the existence of a subthreshold steady-state Na current which to a large extent seems to be balanced by a leak type current.

We used isolated cells mounted in a chamber continuously perfused with solutions of desired composition at 18°C . Membrane potential and membrane currents were recorded under voltage clamp using a single, low resistance (5 – 8 M Ω) intrasomal microelectrode filled with 3 M KCl (ref. 3). This method permitted measurement of steady-state membrane currents that did not exceed 5 nA. Such currents were encountered in a voltage range of 10 – 15 mV in either direction from resting potential (Fig. 1). Steady-state values of the membrane current were determined 10 – 15 s after each polarisation adjustment.

Typical current measurements in the absence and presence of TTX (Fig. 1) show that in control conditions the curve relating membrane current to membrane polarisation had a negative slope starting at depolarisations of 5 – 7 mV. After treatment with 120 nM TTX the current-voltage curve lost this negative slope and became steeper. At the same time, its voltage intercept was shifted in a

negative direction by about 5 mV. In agreement with earlier findings these changes imply a hyperpolarisation as well as a decrease in input resistance in the absence of any injected current.

To see whether these changes originated only in the elimination of a Na conductance, all extracellular Na^+ was replaced by either choline or Tris. In both cases a current-voltage curve was obtained very similar to that encountered after TTX treatment, although potentials were more negative by about 5 mV. This curve underwent no further changes if TTX was added to the Na-free solutions. Thus TTX did not affect the K channel or the leak channel in our preparation and so its effect on the current-voltage relationship, as described above, must have been due to elimination of a specific Na conductance.

For an estimate of the magnitude of this conductance, the current-voltage curves obtained in the absence and presence of TTX, respectively, were subtracted from each other. The resulting relationship between Na current and membrane polarisation (Fig. 1) shows that Na conductance was appreciable in resting conditions and that it did not vanish until the cell was hyperpolarised by at least 10 mV; in depolarising conditions (down to firing threshold) the Na conductance increased at an increasing rate.

To study the nature of the membrane current, I_x , which balances the Na current in resting conditions, cells were exposed to 20 mM tetraethylammonium (TEA) after pre-treatment with 120 nM TTX. In the absence of any injected current this led to a slight depolarisation (2–3 mV) and a minor increase (10–20%) in the input resistance. These changes show—presuming that TEA eliminated the K conductance completely—that in resting conditions only 20–30% of I_x can be attributed to a specific K current. The remaining and greater part of I_x therefore seems to be a leak type current. The ions carrying this current presumably include not only K^+ and Cl^- but also Na^+ . The presence of a Na component in the leak current is suggested by the 5 mV hyperpolarisation that arises in response to removal of all extracellular Na^+ after preceding blockage of the specific Na channels by means of TTX.

Studies of membrane noise³ have suggested that the slowly adapting stretch receptor neurone of lobster has a small tendency for Na inactivation in subthreshold conditions. This type of permeability regulation probably explains the presence of a subthreshold steady-state Na conductance. The functional significance of such a conductance may be twofold. First, as it increases with depolarisation it increases the input resistance of the cell and thus reduces the load on the generator current source. Second, owing to its existence,

Fig. 1 Relationship between membrane current (ordinate) and membrane polarisation (relative to resting potential at -60 mV, abscissa) in the absence (▼), and presence (●) of 120 nM TTX. The relationship between Na current and membrane polarisation (—) was obtained by subtracting the curves I_x and I_m from each other.

Fig. 2 Relationship between membrane current (ordinate) and membrane polarisation (relative to resting potential at -62 mV, abscissa) in control conditions (◆) and after application of TTX to the axon beyond 300–400 μm (▲), and beyond 100 μm from the cell body (■). Difference between curves a and b; ●, difference between curves b and c.

conditions may be fulfilled for the repetitive mode of firing² that is typical of the preparation we used. There is evidence for this latter assumption in the fact that no subthreshold steady-state Na conductance exists in the fast adapting stretch receptor neurone of lobster.

In an attempt to localise the site of origin of the intrasomally detectable subthreshold steady-state Na current, TTX was applied to the axon at various distances from the cell body. As a rule, this resulted in a decrease of the inward component of the membrane current (Fig. 2), indicating that a subthreshold steady-state Na current is generated in the initial parts of the axon as well as in the soma. There was a considerable decrease in inward current even when TTX was applied to relatively distant axonal segments, as shown in Fig. 2. Application of TTX to the axon 300–400 μm from the cell body and beyond gave a marked decrease in inward current. This decrease equalled the further reduction of inward current obtained when extending the treatment about 200 μm towards the cell body. Considering the cable properties of the axon this means that the axonal segments beyond a distance of 300–400 μm from the cell body could generate a stronger inward current than more proximal axonal segments. This may be related to the presence of a spike-trigger zone with particularly developed pacemaker properties about 300–500 μm out on the axon^{4,5}.

Plasma membrane-associated increase in guanylate cyclase activity in regenerating rat liver

CYCLIC GMP has been postulated as one of the intracellular mediators triggering cell growth¹. Exogenously added cyclic GMP or its derivatives are liable to induce a substantial increase in DNA synthesis^{2–4} and to promote growth^{2,5}. Cultured, non-transformed fibroblasts⁶ and lymphocytes¹ exist in one of two reversible growth states, a state of rapid

proliferation and a state of relative quiescence and increased levels of cyclic GMP are correlated with the transition from the resting to the growth state^{1,3}. In these systems, a variety of mitogenic agents have been shown to initiate proliferation of quiescent cells and this effect seems to be accomplished by interaction with the cell surface¹. Therefore, if an increase in cyclic GMP levels were to act as the intracellular signal triggering cell proliferation, its formation and/or degradation should be linked to events occurring in the plasma membrane. Indeed, a membrane-bound guanylate cyclase (GTP pyrophosphatase, cyclising, EC 4.6.1.2.) of cultured fibroblasts has been found to be activated by a fibroblast growth factor⁷.

Partial hepatectomy induces the remaining liver cells to undergo a change from a resting to a proliferating state similar to the one cited above for cultured cells⁸, and the regenerating liver after partial hepatectomy presents a well defined model system for studying cell proliferation *in vivo*. In the normal hepatocyte, however, most of the guanylate cyclase activity is recovered in the cytosol⁹. We therefore examined the possibility that an altered sub-cellular distribution of guanylate cyclase might be found in proliferating liver cells. Data presented show an increase in guanylate cyclase activity in liver homogenates after partial hepatectomy, mainly due to an increase in plasma membrane-associated activity.

We measured cyclic GMP formation in the total homogenate (for details of preparation, see Fig. 1) of regenerating rat liver at different times after partial hepatectomy. An increase in guanylate cyclase activity was observed within 16 h, reaching a maximum 24 h after the operation (Fig. 1). This increase in guanylate cyclase activity correlates with the increase in proliferating activity⁸. At 4 d after hepatectomy, when the regeneration is nearing completion, the elevated cyclic GMP formation returned to control values.

In the quiescent liver, guanylate cyclase is mainly detectable in the soluble fraction (Table 1). At 3 d after partial hepatectomy, the activity of the soluble guanylate cyclase did not change, whereas the plasma membrane-associated enzyme activity rose to about 11 times the value of sham-operated rats. Essentially the same changes were observed when the activities were expressed as pmol cyclic GMP formed per min per g liver (Table 1). Triton X-100 stimulates guanylate cyclase activity in a number of systems^{7,9,11}. Treatment of plasma membrane fractions from normal and regenerating liver with this detergent (Triton:protein=2:1, w/w; 10 min at 0 °C) increased cyclic GMP formation 2.5–2.9 and 2.4–2.6-fold, respectively (three experiments). Thus, approximately the same increase in plasma membrane-associated guanylate cyclase activity was observed in the presence and absence of detergent. The technique used for the isolation of liver plasma membranes, aimed at obtaining the highest possible purity, makes losses of material inevitable. Using the recovery of 5'-nucleotidase (a marker enzyme for liver plasma membranes¹³) as reference, the yield of plasma membrane material in our preparations is about 11%. Table 1 indicates that more than 85% of the increased guanylate cyclase activity in regenerating liver should be localised in the surface membranes.

Rapidly growing tissue is found also in hepatoma tumours. In previous reports, no correlation between cyclic GMP levels and growth rate of hepatoma tumours was found, although cyclic GMP concentrations tended to be higher in hepatoma cells compared with normal liver^{14,15}. We examined guanylate cyclase activity in four hepatoma lines: Morris hepatomas 7777, 9618A₂, 7800 and 9121, the first two lines being rapidly-growing, the others medium-growing tumours. No detectable activity (less than 0.8 pmol cyclic GMP formed per min per mg protein) was found in three lines and an increased activity with respect to normal

liver in line 9121 (25.6±2.8 pmol per min per mg protein; three experiments). Treatment with Triton X-100 did not elicit detectable activity in 7800, 9618A₂ and 7777 lines, although cyclic GMP formation was moderately stimulated in 9121 line (1.6-fold). Addition of hepatoma homogenate without detectable guanylate cyclase activity to normal liver or to the 9121 line did not reveal the presence of enzyme inhibitors. We postulate that a normally functioning guanylate cyclase is essential for growth regulation.

In young adult rats as used in the present experiments,

Fig. 1 Cyclic GMP formation in liver homogenates at various times after partial hepatectomy. Female Buffalo rats (150–200 g) were fed Altromin R, containing 19% protein, and water *ad libitum*. For partial hepatectomy two-thirds of the liver were removed. Sham-operated animals were used as controls. All surgical operations were carried out under ether anaesthesia in the morning between 0800 and 0900. For determinations of guanylate cyclase activity in the total homogenate, in the soluble and crude particulate fraction 0.5 g liver was homogenised in 3 volumes 10 mM Tris-HCl buffer, pH 7.4. Soluble and crude particulate fractions were obtained by centrifugation of the homogenate at 105,000g for 60 min. The pellet was washed once in the same buffer. Plasma membranes were prepared by a modified procedure of Neville's method¹⁰. The total homogenate and the soluble fraction could be stored for several weeks at –40 °C without loss of guanylate cyclase activity. The guanylate cyclase bound to the membrane, however, was highly unstable; the activity of a plasma membrane fraction stored for 2 d at –40 °C decreased by 50%. Rats were killed at the times indicated after partial hepatectomy and suitable dilutions (30–95 µg protein) of a 1:3 (w/v) liver homogenate assayed for guanylate cyclase activity as described previously¹¹ with two modifications: 0.1 mM papaverine was included in the reaction mixture to inhibit cyclic nucleotide phosphodiesterase activity; as rather low activities had to be measured in some fractions, the eluate of the Al₂O₃ columns was further chromatographed on Dowex 1×8 (formate form)¹². This step was very effective in lowering the blank values, which did not exceed 0.006% of the total radioactivity. Preliminary experiments showed that the MnCl₂ concentration used (8 mM) gave maximum activities in control and regenerating liver. Mean ± s.e.m. is given for 4 to 11 animals except for the 2.5 and 16-h values, where the figures for 2 animals are shown. Mean ± s.e.m. for 8 sham-operated rats is indicated by the horizontal bar. There were no differences between sham-operated animals killed 1–4 d after surgery. *Values significantly different from controls ($P < 0.005$).

* Increase in guanylate cyclase activity expressed as pmol cyclic GMP per min per g liver.

Rats were killed 72 h after partial hepatectomy. This time was chosen to minimise possible nonspecific effects of surgery. The plasma membrane fraction was comprised of fractions M₁ and M₂ from modified Neville's¹⁰ method. Aliquots of a liver homogenate and of the various fractions which were in 10 mM Tris-HCl buffer (pH 7.5) were assayed for guanylate cyclase activity. Three dilutions (30–95 µg protein for total homogenate and supernatant, 40–140 and 16–100 µg for the 105,000g pellet and the plasma membrane fraction, respectively) of all fractions were tested to ensure that the reaction velocity was proportional to enzyme concentration. No measurable hydrolysis of added cyclic GMP by phosphodiesterase occurred in any assay. Values are means ± s.e.m. for 4–11 animals. Difference significant † *P* < 0.001 (‡ *P* < 0.005) from sham-operated controls.

DNA synthesis starts to increase 12–15 h after partial hepatectomy, peak values being attained at 19–25 h (refs 8 and 16). Mitosis follows DNA synthesis by about 8–9 h (ref. 8) and it has been estimated that about 40% of the parenchymal cells divide between 30 and 40 m (ref. 16). Thus the timing of the observed increase in guanylate cyclase activity correlates well with the onset of proliferative activity after partial hepatectomy, indicating that the induction of liver cell proliferation is intimately connected with increased activity of this enzyme. Fast transient increases in cyclic GMP concentrations have been reported to occur in several *in vitro* systems^{1,3,7} after administration of mitogenic agents, which presumably interact solely with the cell surface. The fact that the increment is predominantly, if not exclusively, located in the plasma membrane also indicates that in the regenerating liver cyclic GMP acts as signal to mediate growth-initiating signals¹⁷ from the cell surface to intracellular structures (for example, the nucleus). In agreement with this hypothesis, a guanylate cyclase associated with a plasma membrane fraction of mouse fibroblasts was found to be activated by a fibroblast growth factor⁷.

During the preparation of this manuscript, Kimura and Murad¹⁸ reported on an increase in particulate guanylate cyclase activity in regenerating liver. These authors describe a less than twofold increase in guanylate cyclase activity in a plasma membrane fraction of regenerating rat liver compared with the more than 11-fold increment observed here; and we cannot confirm a decrease in the soluble enzyme activity during liver regeneration. Kimura and Murad measured an increased enzyme activity in Morris hepatoma 3924A. Using Morris hepatoma 9121 we also measured increased guanylate cyclase activity, but in three other lines (7777, 7800, and 9618A₂) no enzyme activity could be detected. These contradictory findings in Morris hepatomas demonstrate that no simple correlation between proliferation of normal tissue and malignant growth is possible.

Increases in cyclic GMP levels in brain and liver with sodium azide an activator of guanylate cyclase

SODIUM azide produces extrapyramidal symptoms with necrosis of the cerebral cortex, cerebellum, and basal ganglia. Toxicity with this metabolic inhibitor may also include hypotension, blindness and hepatic necrosis^{1–5}. Many hormones and drugs mediate their effects by altering the intracellular levels of cyclic AMP and/or cyclic GMP^{6–10}. We found that NaN₃ increases cyclic GMP levels in incubations of slices from cerebral cortex, cerebellum or liver, and also stimulates guanylate cyclase activity. In contrast to other agents that can increase cyclic GMP accumulation in tissues the effect of NaN₃ is observed in the absence of added calcium.

In slices from cerebral cortex, cerebellum and liver cyclic GMP levels increased within 5 s after the addition of 1 mM NaN₃ and, in 1–5 min, reached maximal levels (two to fivefold increases) that were maintained for 10 min (Fig. 1). With 1 mM NaN₃ there was no change in the level of cyclic AMP in these tissues at any of the times (5 s–10 min) examined. The accumulation of cyclic GMP in cerebral cortex slices depended on the concentration of NaN₃. NaN₃ (0.15 mM) produced a half-maximal effect and 1 mM NaN₃ was maximally effective. NaCN, another metabolic inhibitor, had little or no effect on cyclic GMP or cyclic AMP levels in cerebral cortex incubations (Table 1). Atropine (0.01 mM), (±)-propranolol (0.01 mM),

Fig. 1 Effect of NaN_3 on cyclic GMP levels in slices of cerebral cortex (●), cerebellum (○) and liver (□). Male Sprague-Dawley rats (150–200 g) were decapitated and slices of cerebral cortex, cerebellum and liver were incubated at 37 °C for 60–90 min in Krebs–Ringer bicarbonate (KRB) medium with 95% O_2 and 5% CO_2 . Slices were washed with fresh medium and incubated with 1 mM NaN_3 for the times indicated. Incubations were terminated by addition of 5% TCA and homogenised. Cyclic GMP and cyclic AMP were purified and assayed as described previously^{11–13}. Guanylate cyclase activity was determined as described previously¹³. Protein was estimated by the method of Lowry *et al.*¹⁴. Values presented are means from 2 to 10 incubations and are expressed as % control. Vertical bars indicate 1 s.e. Control values for cyclic GMP are 0.41 ± 0.09 ($n = 10$), 14.5 ± 2.5 ($n = 10$) and 0.06 ($n = 2$) pmol per mg protein for cerebral cortex, cerebellum and liver, respectively. * $P < 0.05$.

phenoxybenzamine (0.012 mM), diphenhydramine (0.1 mM), and γ -aminobutyric acid (1 mM) had no effect on cyclic GMP or cyclic AMP levels in cerebral cortex or cerebellum incubations with or without 1 mM NaN_3 . Hydroxylamine (0.1 mM), an agent that increases the concentration of γ -aminobutyric acid in brain⁶, markedly increased cyclic GMP levels in slices of cerebral cortex (Table 1). Aminooxyacetic acid (1 mM) which increases γ -aminobutyric acid levels in brain⁶, had no effect, however, on cyclic GMP or cyclic AMP levels in incubations of cerebral cortex slices with or without 1 mM NaN_3 .

The stimulatory effects of NaN_3 and NH_2OH on cyclic GMP accumulation were additive (Table 1).

The accumulation of cyclic GMP in incubations of cerebral cortex slices with 1 mM NaN_3 was unaltered when calcium-free medium was used (Table 1). The increase in cyclic GMP levels with 80 mM KCl, a depolarising agent at this concentration, required the presence of Ca^{2+} . The presence or absence of 2.5 mM Ca^{2+} in the incubation medium had a small effect on basal cyclic GMP levels. These results indicate that there are at least two mechanisms to increase cyclic GMP levels in tissues—

Fig. 2 Effect of NaN_3 on soluble (○) and particulate (●) guanylate cyclase from cerebral cortex. Rat cerebral cortex was homogenised at 4 °C in 9 volumes 0.25 M sucrose containing 5 mM Tris-HCl buffer, pH 8.0, using a glass homogeniser with a Teflon pestle. Homogenates were filtered through gauze and centrifuged at 105,000g for 60 min to separate soluble and particulate fractions. Enzyme preparations (20–50 μg protein) were preincubated for 5 min at 37 °C in mixtures of 50 mM Tris-HCl buffer, pH 7.6, 10 mM theophylline, 15 mM creatine phosphate, 20 μg creatine phosphokinase (120–135 U mg^{-1}), with or without NaN_3 as indicated, in a final volume of 100 μl . Reactions were started by addition of 3 mM MnCl_2 and 1 mM GTP (final concentrations), incubated for 5 min and terminated by adding 0.9 ml 50 mM Na acetate buffer, pH 4.0, and heated for 3 min at 90 °C (ref. 13). Cyclic GMP formed was determined by radioimmunoassay. Values presented are means of duplicate determinations.

Table 1 Effects of NaN_3 and other compounds on cyclic nucleotide levels in slices of cerebral cortex in the presence and absence of Ca^{2+}

Addition	Incubation time (s)	Cyclic GMP (pmol per mg protein)		Cyclic AMP (pmol per mg protein)	
		KRB medium	Calcium-free medium	KRB medium	Calcium-free medium
None	—	0.77	—	2.85	—
NaCN (1 mM)	60	1.01	—	3.03	—
None	—	0.41	—	3.74	—
NH_2OH (0.1 mM)	60	2.74	—	2.88	—
NaN_3 (1 mM)	60	1.78	—	3.48	—
NH_2OH (0.1 mM) + NaN_3 (1 mM)	60	4.21	—	2.88	—
None	—	0.16	0.24	2.42	3.19
NaN_3 (1 mM)	15	0.44	0.85	2.72	3.23
NaN_3 (1 mM)	60	1.03	2.08	2.77	3.07
None	—	0.19	0.54	1.28	1.53
KCl (80 mM)	60	0.39	0.56	1.58	1.64
KCl (80 mM)	300	2.75	0.28	1.72	1.82

Cerebral cortex slices were incubated, washed with calcium-free KRB medium with 0.1 mM EGTA, and incubated an additional 30 min before NaN_3 or other agents were added. Slices were incubated with compounds indicated in the presence and absence of Ca^{2+} . Incubations were terminated by addition of 5% TCA and homogenised. Cyclic nucleotides were determined as described previously^{11–13}. When media containing no Ca^{2+} or high K^+ were used, the concentration of Na^+ was changed to maintain the total concentration of cation at 150 mM. Values presented are means of duplicate incubations.

one calcium-dependent and the other apparently calcium-independent.

The soluble and particulate guanylate cyclase activities in tissues have different properties and can be separated with gel filtration techniques¹³. Soluble guanylate cyclase demonstrates typical Michaelis-Menten kinetics and is activated by calcium. Particulate guanylate cyclase, which is associated with plasma membranes, Golgi and endoplasmic reticulum, is an allosteric enzyme and inhibited by calcium¹³. Soluble and particulate guanylate cyclase in cerebral cortex were examined, and we obtained results similar to those reported for other tissues. The particulate enzyme from cerebral cortex was markedly stimulated by NaN_3 , whereas NaN_3 had no effect on soluble guanylate cyclase (Fig. 2). The stimulation of particulate guanylate cyclase depended on the concentration of NaN_3 , with half-maximal activation occurring with 0.3 mM NaN_3 , a concentration similar to that required with slices. NH_2OH was a more potent stimulator of the particulate enzyme, but not the soluble enzyme from cerebral cortex. Half-maximal activation was obtained at 7 μM NH_2OH . Activation of guanylate cyclase by NaN_3 did not result from the preservation of substrate (GTP) or the inhibition of cyclic nucleotide phosphodiesterase activity. Various halide ions and cyanide (1 mM) had no effect on either soluble or particulate guanylate cyclase.

The presence of two forms of guanylate cyclase¹³ in tissues in which one is activated and the other is inhibited by Ca^{2+} may be the explanation for our observations. Generally the inhibitory effects of NaN_3 with a variety of enzymes require higher concentrations than those used in this study¹⁶. Cyanide, another metabolic inhibitor, had small effects on cyclic GMP levels and guanylate cyclase activity. The effects of NaN_3 and NH_2OH are probably not due to general inhibition of intracellular metabolism. Although the effects of NaN_3 on guanylate cyclase can explain the increased accumulation of cyclic GMP observed with intact tissues, other effects of NaN_3 cannot be excluded. NaN_3 and NH_2OH are known to be strong nucleophilic substances. Additional studies are also needed to determine whether or not the toxic manifestations of NaN_3 are related to the stimulation of guanylate cyclase and increased cyclic GMP accumulation in tissues.

Positive control of cyclic AMP on mesenchymal factor controlled DNA synthesis in embryonic pancreas

THERE is increasing evidence that cyclic AMP and/or cyclic GMP are involved in the regulation of a number of metabolic processes including cell proliferation¹⁻¹³. We report here the results of an investigation testing the effects of cyclic AMP, cyclic GMP and the mesenchymal factor (MF)¹⁴⁻¹⁷ on the stimulation of DNA synthesis in embryonic epithelia in organ culture.

The normal development of most organ systems requires the interaction of epithelial and mesenchymal cells^{18,19}. We have used the pancreas as a paradigm for the epithelial-mesenchymal interaction. A factor obtained from mesenchymal tissues or from mesenchyme-rich embryonic tissues can substitute for the mesenchyme to induce normal growth and development¹⁴⁻¹⁷. MF activity is sensitive to both trypsin¹⁵ and periodate oxidation (ref. 17, and S. Levine, R. P. and W. J. R., unpublished observations), suggesting that protein and carbohydrate moieties are required for its function. Purified MF covalently bound to Sepharose beads induces DNA synthesis in the pancreatic epithelial cells. The experimental results suggest that MF functions through an interaction with the cell surface^{16,17}. The effects of MF may therefore be mediated by secondary messengers such as cyclic AMP or cyclic GMP. We have therefore tested the effects of these compounds as well as

Fig. 1 The incorporation of ^3H -thymidine in the presence of inactivated MF and cyclic AMP is due to the labelling of many cells. Pancreatic epithelia were isolated and cultured as described in Table 1 in medium containing 1 mg ml⁻¹ of inactivated factor in the presence (a) or absence (b) of 10^{-3} M 8-OH-cyclic AMP. The epithelia were harvested and fixed in 4% glutaraldehyde in 0.04 M phosphate buffer (pH 7.4). After postfixation in osmium they were embedded in Epon²⁰. Thick sections were placed on the slides and coated with an Ilford L-4 emulsion²⁰ and developed after 10 d of exposure. After 90 min of treatment with sodium periodate MF is not totally deprived of activity: by increasing its concentration there is higher thymidine incorporation (see Fig. 2b) than is reflected by a few labelled cells in Fig. 1b. But the addition of 8-OH-cyclic AMP increases dramatically the number of cells which undergo DNA synthesis (Fig. 1a). The vacuoles observed are caused by the addition of cyclic AMP and probably reflect the increased fluid transport into the existing exocrine lumen which is already present at that time of development²¹.

their derivatives on the DNA synthesis of pancreatic epithelia (mesenchyme-free) in the presence and absence of MF. None of the compounds affected MF activity; but unexpectedly, MF which had been inactivated could be completely reactivated by inclusion of dibutyryl cyclic AMP (db-cyclic AMP) or 8-OH-cyclic AMP though not by cyclic AMP, cyclic GMP or cyclic GMP analogues. The effects of 8-OH-cyclic AMP and 8-Br-cyclic GMP on DNA synthetic activity in the presence of MF or inactivated MF are summarised in Table 1. Neither 8-OH-cyclic AMP nor 8-Br-cyclic GMP stimulated or inhibited DNA synthesis when the epithelia were incubated in the presence of active MF. On the other hand, 8-OH-cyclic AMP but not 8-Br-cyclic GMP stimulated the activity of periodate-inactivated MF to the levels of incorporation observed with untreated MF. We have shown previously that in the presence of MF, ^3H -thymidine is incorporated into the DNA in many cells, whereas, in contrast, incubation with inactivated MF leads to ^3H -thymidine incorporation in very few cells¹⁷. Figure 1a and b demonstrates that the addition of 8-OH-cyclic AMP increases thymidine incorporation into cells in the presence of inactivated MF. Thus the effect of cyclic AMP is to increase the proportion of cells undergoing DNA synthesis. The specificity of this response is reported in Table 2. Whereas 8-OH-cyclic AMP and db-cyclic AMP stimulate DNA synthesis in the presence of inactivated MF, neither 5'-AMP nor cyclic AMP itself even when present with the phosphodiesterase inhibitor, caffeine, promote DNA synthesis. Some MF preparations that become inactive spontaneously can also be activated by db-cyclic AMP derivatives. The activation of DNA synthesis by db-cyclic AMP or 8-OH-cyclic AMP but not cyclic AMP is taken to mean that entrance into the cells is a requisite for activity. All attempts to reactivate the factor itself by treatment with cyclic AMP or cyclic AMP analogues before its addition to the cells have failed. For example, inactivated MF incubated for 20 h at 37 °C with 10^{-3} M db-cyclic AMP is inactive after removal of the free cyclic nucleotides by chromatography on Sephadex G-25, but stimulates DNA synthesis on addition of db-cyclic AMP into the culture medium. The incorporation of ^3H -thymidine into DNA is dependent on both the concentration of inactivated MF and 8-OH-cyclic AMP. As shown in Fig. 2a, increasing the concentration of inactive factor in the presence of 10^{-3} M 8-OH-cyclic AMP results in an increase of thymidine incorporation into DNA. In fact, the saturation profile is similar to that observed with active MF alone¹⁷. In the presence of a single concentration of MF (Fig. 2b), addition of 8-OH-cyclic AMP gives a typical hyperbolic activation profile (low levels of activity are always found with periodate inactivated MF preparations). The activation

Table 1 Inactivated MF stimulates DNA synthesis in the presence of cyclic AMP but not cyclic GMP

Inactivated MF stimulates DNA synthesis in the presence of cyclic AMP but not cyclic GMP. Pancreatic epithelia were isolated from rat embryos on day 12 of gestation (about 35 somites) as previously described¹⁴⁻¹⁷. Individual epithelia were transferred in Dispo tray wells (Linbro, Los Angeles) and cultured for 18 h in 100 μl of medium (Eagle's basal medium in which the essential amino acids have been increased sevenfold ($7 \times \text{BME}$), plus 1 mg ml^{-1} bovine serum albumin, 1 μg , ml^{-1} penicillin, 10^{-4} mg ml^{-1} streptomycin and 25 μg ml^{-1} fungisone) in an atmosphere of 5% CO_2 in air. The nucleotides were dissolved in the $7 \times \text{BME}$; and 100 μl of this solution was added per ml of culture medium. Dilutions were made from a 10^{-3} M stock solution which was kept frozen at -70°C . Inactivated MF or MF was present at a final concentration of 600 μg protein ml^{-1} . For assays of DNA synthesis the epithelia were further incubated for 6 h in fresh identical culture medium containing ^3H -thymidine (10 μCi ml^{-1}). At the end of this period the epithelia were harvested, washed three times with EBSS containing 0.1% albumin, transferred into microfuge tubes (Beckman) and frozen. To measure the thymidine incorporated 100 μl 0.1% SDS was added and the tissue was disrupted by sonication at 0°C by rubbing the probe of the sonicator along the tube for 30 s. Aliquots (40 μl) of the suspension were spotted on GF Whatman filters. The filters were washed 6 times with cold 5% TCA, 3 times with 95% ethanol and twice with ether. The filters were dried and counted in scintillation fluid (100 ml NCS, 16 ml H_2O , 15.3 g Omnifluor added to 3.8 l of toluene). Results are expressed as c.p.m. ^3H -incorporated per epithelium during the 6-h incubation in the presence of ^3H -thymidine. MF was prepared as described¹⁶. For oxidation with sodium periodate, MF in 0.8 M KCl, 0.01 M Tris-HCl buffer (pH 8.0) was dialysed against 0.1 M glycine buffer at pH 8.0. After being dissolved in the same buffer sodium periodate was added at a final concentration of 50 mM. The reaction was allowed to proceed at 0°C in the dark for 90 min. To stop the oxidation tenfold molar excess of glycerol was added. After 15 min the periodate-treated MF (IO_4MF) was dialysed against 0.1 M glycine buffer (pH 8) followed by dialysis against 0.1 M glycine (pH 9). The preparation was then treated with sodium borohydride, dissolved in 0.1 M NaOH and added at a final concentration of 0.1 M. The preparation ($\text{IO}_4\text{BH}_4\text{MF}$) was dialysed against 0.01 M glycine buffer (pH 9). This fraction is referred to as inactivated MF. Identical results have been obtained if IO_4MF is not reduced with sodium borohydride. The effect of the oxidation seems specific: control experiments (S. Levine, R.P., and W.J.R., unpublished) show the sodium periodate is not toxic by itself since simultaneous addition of IO_4Na and glycerol have no effect on MF activity no more than direct reduction of MF by NaBH_4 . The inactivation by oxidation does not result from activation of an inhibitor since mixing of MF and IO_4MF does not decrease the activity of MF. The numbers in parentheses represent the lowest and highest values. *n* indicates the number of epithelia assayed.

Fig. 2 The degree of stimulation of DNA synthesis is dependent on the concentration of both inactivated MF and the cyclic AMP derivative. Pancreatic epithelia were isolated, cultured and DNA synthesis measured as described in Table 1. a, 9 epithelia were cultured in the presence of various concentrations of inactivated factor in the presence (●) or absence (○) of 10^{-3} M 8-OH-cyclic AMP. Periodate borohydride treated MF was concentrated up to 14 mg ml^{-1} in an Amicon stirred cells (Amicon Corp., Lexington, Massachusetts) using a PM-10 filter. The intermediate concentrations were obtained by dilution from that stock solution and added as usual at 100 μl ml^{-1} . The increase of thymidine incorporation in epithelia cultured in the presence of concentrated inactivated MF is due to the fact that after 90 min oxidation there is some remaining activity. b, Sets of 9 epithelia were cultured in the presence of 300 μg ml^{-1} of inactivated MF and various concentrations of 8-OH-cyclic AMP. The bars represent the s.e.m. of the tritium counts.

Table 2 DNA synthetic activity in the presence of inactive MF is dependent on cyclic AMP

	Nucleotides (10^{-3} M)	^3H -Thymidine incorporation into DNA (c.p.m. per epithelium per 6 h)	<i>n</i>
Inactivated MF	—	160 (128/190)	9

Inactive MF	—	205 (116/392)	5
Inactive MF	db-cyclic AMP	9,361 (7,625/10,795)	6

DNA synthetic activity in the presence of inactive MF is cyclic AMP dependent. Experiments were carried out as described in the legend of Table 1. Inactivated MF was present at a concentration in the incubation medium of $300 \mu\text{g ml}^{-1}$ and inactive MF at $600 \mu\text{g ml}^{-1}$. Inactive MF refers to MF preparations which spontaneously lose activity upon storage at 0°C . In such conditions, MF may lose its activity in a few days, but such inactive MF as well as IO_4MF or $\text{IO}_4\text{BH}_4\text{MF}$ are reactivated by cyclic AMP derivatives even after weeks of storage at 0°C . The numbers in parentheses represent the lowest and highest values. *n* represents the number of epithelia assayed

profile of db-cyclic AMP is different: a peak of activity is reached between 5×10^{-3} and 10^{-3} M. At higher concentrations inhibition is observed, perhaps because of the accumulation of toxic levels of butyrate.

As shown in Table 3, inactive MF is required for the activation of DNA synthesis. Cyclic GMP or cyclic GMP derivatives do not stimulate DNA synthesis by themselves. Furthermore, addition of varying concentrations of 8-Br-cyclic GMP in the presence of optimal levels of 8-OH-cyclic AMP do not induce DNA synthesis in the absence of inactivated MF (Table 3). These experiments give no evidence for a role of cyclic GMP as an intermediate in the action of MF.

Several processes that are dependent on cyclic AMP have been shown to require or involve calcium²⁰. In these systems calcium ionophores frequently influence the process²¹⁻²⁴. We have therefore investigated the effect of the calcium ionophore A23187 on DNA synthesis in the pancreatic epithelia. This compound at levels between 10^{-7} and 10^{-6} M does not stimulate the incorporation of ^3H -thymidine into DNA. In fact, at the highest concentrations tested (4×10^{-7} and 10^{-6} M) there is inhibition of the usual stimulation produced by inactive MF and 8-OH-cyclic AMP. We consider the experiments with calcium ionophore equivocal because these compounds allow transport of other ions and are present over relatively long periods of time (24 h) during which the stimulation of incorporation of precursors into DNA is observed.

The results of the present investigations suggest that our mesenchymal factor preparations contain two functional activities. This may explain our previous difficulties in

purification of MF and suggests that assays in the presence of 8-OH-cyclic AMP may detect one component, and that assays in the presence of inactive factor detect another function. The results of the present experiments suggest that one function, perhaps requiring a carbohydrate moiety (because of the sensitivity to periodate oxidation), may act through the enhancement of intracellular levels of cyclic AMP. The evidence for this is admittedly indirect, since intracellular levels of cyclic AMP have not been measured. The specificity of the response for cyclic AMP derivatives which penetrate cells and the magnitude of the response are, however, compatible with this view. The mode of action of cyclic AMP in this system is not yet resolved and an indirect effect of cyclic AMP is possible: intracellular cyclic AMP may enhance the responsiveness of the cell to 'inactive factor' by, for example, increasing the density of appropriate receptors on the cell membrane.

It is somewhat unexpected that the cyclic AMP analogues have a positive effect on DNA synthesis. In other experiments involving cells in culture, addition of compounds which increase intracellular cyclic AMP levels inhibit DNA synthesis¹⁻⁴. Furthermore, in a variety of cells there seems to be an inverse correlation between the level of intracellular cyclic AMP and DNA synthesis⁶⁻⁹. There seems also to be a positive correlation between increased cyclic GMP levels and DNA synthesis in some systems¹⁰⁻¹³. These results contrast with the findings reported here. Cyclic AMP is required for DNA synthesis; cyclic GMP or its derivatives have no effect by themselves, and do not inhibit the cyclic AMP response. It is possible that secretory cells whose secretory functions are positively regulated by cyclic AMP may also develop under the positive control of cyclic AMP. The positive control by cyclic AMP is analogous to that inferred in the action of a number of other peptide hormones²⁵⁻²⁸ which apparently act through cyclic AMP. The response observed in the embryonic pancreatic cells may also represent a characteristic of differentiating systems, that is, that high levels of cyclic AMP are required for a differentiative transition. Thus, proliferation of cells undergoing differentiation may have a different regulatory mechanism than the various cell types normally studied in cell culture. The developing pancreatic epithelium may be useful to define the role of cyclic AMP on the regulation of DNA synthesis and cytodifferentiation.

Table 3 Addition of cyclic GMP does not influence DNA synthesis in embryonic pancreatic cells

Protein added to medium	Addition					
	None	8-OH-cyclic AMP (10^{-3} M) + 8-Br-cyclic GMP (M)				
		—	10^{-6}	10^{-5}	10^{-4}	10^{-3}
Inactivated MF	205 (140/330)	1,414 (751/2,112)	2,025 (1,540/2,500)	2,098 (1,230/2,420)	1,978 (650/2,980)	2,452 (1,630/3,100)
Albumin	144 (106/195)	162 (91/233)	178 (71/362)	213 (143/501)	247 (107/552)	303 (210/403)

Addition of cyclic GMP or its derivatives does not influence DNA synthesis of embryonic pancreatic cells. Experiments were carried out in the same way and conditions are as described in the legend for Table 1. Inactivated MF was added at a concentration of about $300 \mu\text{g ml}^{-1}$ and albumin at 1 mg ml^{-1} . The addition of db-cyclic GMP or cyclic GMP in place of 8-Br-cyclic GMP led to identical results. The numbers are the average of 8 or 9 epithelia; the numbers in parentheses correspond to the lowest and highest values.

Ultraviolet light-induced unscheduled DNA synthesis in mouse oocytes during meiotic maturation

ULTRAVIOLET light-induced incorporation of ^3H -thymidine into DNA by non-S-phase nuclei has been observed in cultured mammalian cells¹, spermatogenic cells²⁻⁴, and embryos⁵. This unscheduled DNA synthesis is generally considered to be the result of excision and replacement of ultraviolet-damaged bases by repair enzymes⁶⁻⁸. We have examined the repair capacity of full-grown mouse oocytes after exposure to ultraviolet irradiation. As sensitivity to chemical mutagens and X irradiation changes during meiotic maturation in many species, we determined whether the ability to repair damage to DNA changes during mouse oocyte maturation *in vitro*. Oocytes were found to be capable of unscheduled DNA synthesis during meiotic maturation; however, irradiation of germinal vesicle stage oocytes induced higher levels of ^3H -thymidine incorporation than irradiation at metaphase I or metaphase II stages.

Fully-grown oocytes aseptically isolated from the ovary of adult mice were cultured in chemically defined medium⁹. Oocytes were irradiated 2-18 h after isolation using germicidal lamps, and incubated immediately in medium containing ^3H -thymidine. Non-irradiated oocytes served as controls. Incorporation of ^3H -thymidine into chromosomes was studied by autoradiography.

The progression of meiotic maturation of the oocytes during the culture period is summarised in Table 1. Many of the oocytes underwent germinal vesicle (GV) breakdown within 3 h of isolation. Metaphase I (MI) was reached by 4-8 h after the start of culture. Chromosomes at this stage were short and thick and were usually recognised as pairs of homologues. Oocytes cultured for 16-18 h reached second metaphase (MII), as evidenced by appearance of the first polar body (PBI). Oocyte chromosomes at MII were more clustered than those at MI. Whereas the morphology of the MII chromosomes was

Fig. 1 Unscheduled DNA synthesis in mouse oocytes. *a*, MII control ($\times 1,150$). *b*, MII irradiated (60 J m^{-2} ; $\times 800$). Oocytes were irradiated in isotonic PBS containing 2 mg ml^{-1} polyvinyl pyrrolidone at 2-18 h after isolation using germicidal low pressure mercury discharge lamps (dose rate $1.3 \text{ J m}^{-2} \text{ s}^{-1}$) and immediately incubated in medium containing ^3H -thymidine ($20 \mu\text{Ci ml}^{-1}$; specific activity 40 Ci mmol^{-1}) for 1 h and cultured for 1 h in unlabelled medium. Non-irradiated oocytes served as controls. After washing, all oocytes were fixed (ethyl alcohol-glacial acetic acid, 3:1), placed on microscope slides, and incubated at 37°C in an atmosphere of 45% acetic acid for 5-10 min and air dried. Before dipping the slides in Kodak NTB emulsion, they were soaked in 5% trichloroacetic acid at 4°C for 30 min, washed in 95% ethanol and air dried. Exposure to the emulsion was for 2 weeks.

well preserved (Fig. 1*a*), PBI chromosomes deteriorated, with bridge formation and fusion, into a mass of chromatin.

Autoradiography showed that grain counts over the GV or chromosome set were significantly higher (Student's *t* test, $P < 0.001$) after ultraviolet irradiation than in controls, regardless of the stage of meiotic maturation at which they were irradiated (Table 2, Fig. 1*b*). The corrected oocyte grain count increased with dose at 30 and 60 J m^{-2} but, except for the MI oocyte, there was no further increase in grain count at 120 J m^{-2} . Irradiated PBI had significantly higher observed and corrected grain counts than controls at a dose of 30 J m^{-2} ($P < 0.001$), approximately half that localised over MI or MII chromosomes; but corrected grain counts for the PBI were not significantly above controls when higher doses were given, suggesting that the slight repair capacity of the PBI was lost, perhaps by ultraviolet disruption of polar body integrity.

Grain counts over ultraviolet-irradiated oocytes differed

Table 1 Progression of meiotic maturation in mouse oocytes in culture

Time in culture (h)	No. of oocytes	% Oocytes		
		GV	MI	MI
2-4	108	33	67	0
6-8	12	0	100	0
16-18	120	7	15	78

Fully grown oocytes were isolated aseptically from the ovaries of 8-10-week-old mice (DUB/ICR strain, Flow, Dublin, Virginia) and cultured at 37°C with an atmosphere of 5% CO_2 -95% air in oocyte culture medium⁹.

Table 2 Incorporation of ^3H -thymidine into chromosomes of oocytes

Stage of oocytes	Dose (J m^{-2})	No. of oocytes	Grain counts on GV and chromosomes	
			Observed grains (mean \pm s.e.)	Corrected for background grains (mean \pm s.e.)
GV	0	13	19.6 \pm 7.0	3.8 \pm 6.0
	30	4	182.3 \pm 90.7	126.8 \pm 80.6
	60	13	694.5 \pm 133.0	605.4 \pm 114.6
	120	16	600.9 \pm 155.8	576.7 \pm 149.0
MI	0	23	2.2 \pm 0.8	-4.2 \pm 1.9
	30	8	34.1 \pm 8.9	37.2 \pm 11.7
	60	32	65.4 \pm 10.1	76.7 \pm 11.2
	120	38	83.9 \pm 10.7	89.6 \pm 12.7
MII	0	16	4.9 \pm 2.4	3.2 \pm 1.8
	30	11	30.0 \pm 5.5	29.7 \pm 5.8
	60	11	43.9 \pm 9.9	37.0 \pm 11.3
	120	15	39.3 \pm 6.5	39.5 \pm 7.4
PBI	0	21	2.5 \pm 0.5	-2.2 \pm 2.1
	30	12	18.8 \pm 6.7	15.8 \pm 7.4
	60	49	10.3 \pm 1.7	9.7 \pm 2.2
	120	12	11.4 \pm 3.3	7.6 \pm 4.0

Oocytes were treated as in Fig. 1. Grains on autoradiographs were counted using an ocular micrometer sectioned in $100 \mu\text{m}^2$ areas. Number of grains observed over chromosomes or GV was scored. As the grain density of background as well as the area of the chromosomes or GV varied, however, grain number was corrected for background by the following formula: corrected grain counts = $(A - N)(B/n)$, where N is the number of unit areas in which all chromosomes or GV is confined and A is the total grain number in N areas, n is the number of background unit areas adjacent to the chromosomes or GV, and B is the total grain count in n areas. This correction gave negative values for control oocytes when grain counts over chromosomes were lower than the average background counts.

markedly depending on the stage of meiotic maturation, whereas those of control oocytes invariably remained low (Table 2, Fig. 2). There was a large number of grains on GVs of irradiated oocytes, whereas fewer grains were localised over MI and MII chromosomes, and fewer still over polar body chromosomes. Because of the intervening meiotic reduction division, grain count over a chromosome set at MII should be half that over MI chromosomes, assuming that ultraviolet penetration and tritium self-absorption is the same in both situations. At a dose of 30 J m^{-2} , corrected grain counts over MI and MII chromosomes were not significantly different ($P \approx 0.2$), whereas at 60 and 120 J m^{-2} , MI grain counts were approximately twice those of MII chromosomes. These results suggest that repair capacities are similar at these two stages, although considerably lower than in the intact GV. Because of the high grain counts over GV-2 stage oocytes, compared with later stages, we determined whether there was a decrease in thymidine uptake during oocyte maturation. Samples of 10 oocytes were incubated in $20 \mu\text{Ci ml}^{-1}$ ^3H -thymidine for 1.5 h, washed in isotonic phosphate buffered saline (PBS) and collected on $5 \mu\text{m}$ Millipore filters by suction filtration. Cells were dissolved in 1% Triton X-100 and samples were counted with a liquid scintillation spectrometer. We found that there was no significant difference in uptake between the GV stage (44.2 c.p.m. per egg, three samples) and the MII stage (52.3 c.p.m. per egg, four samples). Thus, it seems that the higher GV grain counts are due to greater levels of thymidine incorporation into DNA, although higher grain counts could result in part from higher autoradiographic efficiency for the flattened GV nuclei than for condensed chromosomes.

In these experiments mouse oocytes exhibit unscheduled DNA synthesis after ultraviolet irradiation, and thus are capable of excision repair of DNA damage at these stages. Spermatogonia and spermatocytes of several mammalian species also exhibit unscheduled DNA synthesis after ultraviolet irradiation²⁻⁴ or exposure to a chemical mutagen, ethyl methane sulphonate¹⁰. In contrast, spermatids and spermatozoa show little or no unscheduled DNA synthesis with these treatments^{2-4,10}. As the excision repair system seems to act on a variety of base alterations¹¹, it may confer some protection against environmental base damage in mammalian germ cells during meiotic maturation.

The dose rate effects for X-ray-induced mutations of mouse oocytes have been interpreted as indicating the presence of an X-ray repair system during oogenesis^{12,13}. Oocyte radio-

sensitivity follows the same pattern in diverse animals, including mice¹⁴⁻¹⁶. During meiotic maturation, mouse oocytes are the least sensitive to X-ray induction of mutations or chromosome aberrations before GV breakdown, then become more sensitive at MI (ref. 17). Although repair of ultraviolet and X-ray damage to DNA involves several distinct processes, the base-damage component of X-ray damage could probably be repaired during meiotic maturation stages of oocytes, and changes in excision repair capability may account in part for the known changes in X-ray sensitivity. In addition to providing protection from genetic damage at meiotic maturation stages, the excision repair capacity seen here may contribute to the repair capabilities that have been observed in early stages of mouse embryos⁵.

Duplex microtubule is a new form of tubulin assembly induced by polycations

INTACT microtubules surrounded by a coat of extra material and stabilised by polycations such as Alcian blue, have been seen by Behnke¹ in brain extracts. A similar structure was reported in preparations of microtubules reassembled *in vitro* when DEAE-dextran was added (ref. 2) and the extra material was attributed to DEAE-dextran itself. In this note and the accompanying communication by Behnke³ evidence is presented that the outer component is an additional shell of tubulin subunits probably complexed with polycations. This structure is related to a double ring form of tubulin, which is a putative nucleating centre for microtubule assembly.

Highly purified tubulin prepared from pig brain⁴ was polymerised at 37 °C to form microtubules. Protamine was added at a twofold molar excess over protein, and there was an immediate increase in turbidity. The microtubules, which had the characteristic 40 Å axial periodicity and 250 Å diameter, were surrounded along their length by an outer wall which had an overall diameter of 380 Å as Fig. 1 shows. Apart from some protamine, protein estimation and sodium dodecyl sulphate (SDS) gel electrophoresis show that the protamine-treated tubules consist of tubulin (97%) and the high molecular weight components known to be associated with microtubules². Too little non-protein material is present (< 10%) to account for the outer wall. Since this structure is formed with such a variety of polycations^{2,3} and consists almost entirely of tubulin, it is a new tubulin assembly which we propose to call a duplex microtubule.

When protamine at less than equimolar concentration with respect to protein is added, regions of both duplex and microtubule are seen along any one length of tubule (Fig. 1a). The protofilamentous appearance of the microtubule is also visible at the centre of the duplex, whereas the predominant feature of the outer wall, seen clearly at the edges of the complex, is an axial repeat of 50 Å. Optical diffraction patterns of the duplex structure (Fig. 2) are consistent with these observations. Weak but clear off-meridional reflections corresponding to an axial spacing of 40 Å are seen which are characteristic of patterns from axonemal⁵ and reconstituted⁶ microtubules. Also there are strong off-meridional reflections at $1/50 \text{ Å}^{-1}$ which we have associated with a helical arrangement of subunits in the outer wall. The whole structure contributes to the equatorial pattern and for this reason the other reflection characteristic of microtubules, namely an equatorial at 50 Å (refs 5 and 6) has not been clearly identified. The pattern also shows other reflections; these and the ones we have described indicate that the duplex structure is complex. A simpler structure which resembles the outer wall by itself is, however, obtained by adding spermine to tubulin at 4 °C. (Fig. 1c). Its diameter is similar to that of the duplex tubule and the 50-Å axial periodicity can be seen. Its diffraction pattern (not shown) shows the strong 50-Å off-meridional spots and in addition strong near equatorial reflections at a spacing corresponding to 40 Å. The dimensions of this lattice (50 Å axially \times 40 Å azimuthally) are therefore the same as the size of the subunits in a microtubule (40 \times 50). This implies that the subunits in both the inner and outer wall of the duplex tubule are the same but oriented perpendicular to each other in the two layers of the complex.

The structure of the duplex microtubule was investigated further by comparing its stability with that of microtubules at 4 °C. The ring forms produced on cooling are summarised in Table 1. Microtubules, in the absence of protamine, are completely dissociated after 30 min at 4 °C into single rings of outer diameter 380 Å, inner diameter

250 Å (30–36S protein)^{2,7} and particles, possibly dimers (6S protein)^{2,7}. These single rings have the same outer diameter as the duplex tubules and are approximately the same as the outer diameter of the single rings, double rings and helices reported previously for similar conditions^{2,8}.

In the presence of protamine, duplex and microtubules are seen even after 1 h at 4 °C as well as single rings and double rings (Fig. 1b). Both these rings have the same outside diameter as the duplex microtubules (Table 1) as seen fortuitously in Fig. 1b where a ring is superimposed on a tubule. Double rings together with short segments of duplex

Fig. 1 Polymorphic forms of tubulin. *a*, Regions of duplex microtubule induced by low levels of protamine. Microtubules from purified tubulin⁴ (10 μM) in reassembly buffer (100 mM MES, 1 mM EGTA, 0.5 mM Mg^{2+} , 1 mM GTP, pH 6.8) were incubated with neutralised protamine (5 μM). ($\times 150,000$.) *b*, Duplex tubules cooled at 4 °C for 1 h. The preparation shows both undissociated duplex tubules and ring forms. The fortuitous superposition of the single ring on the duplex tubule illustrates that their diameters are the same. ($\times 250,000$.) *c*, Spermine-induced tubule formation. Purified tubulin (1.8 μM) was incubated at 4 °C with neutralised spermine (1.5 μM), giving rise to a structure resembling the outer wall of the duplex structure. ($\times 250,000$.) Samples for electron microscopy were negatively stained with 2% uranyl acetate.

Fig. 2 Optical diffraction pattern of a duplex tubule showing 40-Å microtubule reflections and the 50-Å off-meridional reflections from the outer wall. The 50-Å reflections are also seen in patterns from spermine induced tubules.

again with diameter 380 Å were formed by adding protamine to tubulin at 4 °C, (Fig. 3). These rings are so well preserved that often 13 subunits (the number of protofilaments in a microtubule) can be counted in the inner ring (Fig. 3, inset). Significantly the outer diameter of this inner ring is 250 Å, the same as the microtubule. The double ring therefore has the same cross section as the duplex (Table 1). The subunits in the outer ring cannot be counted, suggesting that the molecules are differently arranged.

Some of the structures induced by polycations may also be formed *in vivo*. The duplex microtubule is seen occasionally in brain extracted with a special microtubule stabilising medium¹. Macrotubules of diameter about 340 Å are formed in cells subjected to cold⁹, high pressure⁹ and drugs¹⁰. One form¹⁰, in particular, is found in the presence of vinblastine, itself a polycation. It is not, however, clear from these observations whether these structures are the same as the duplex tubule or the outer wall, as in the spermine-generated tubules.

The formation of the duplex tubule *in vitro* may provide clues to the mechanism of microtubule assembly which is at present unclear. Previous suggestions have involved the unrolling of rings into protofilaments^{7,8}, or the rearrangement of stacks of rings into a helix², but both pro-

posals require large subunit rearrangement. Another possibility follows from the observations presented here. Before tubule formation the dominant form, at least in our preparations, is the 380-Å diameter single ring (or short segment of helix). A ring form (although not necessarily the same one for each proponent) is generally agreed to be a necessary step in polymerisation and a factor which converts 6S protein to a ring form has been described by Weingarten *et al.*¹².

Fig. 3 Double rings and short segments of duplex tubule seen when protamine is added to tubulin at 4 °C. Insert shows double ring with 13 subunits in the inner ring. The samples were negatively stained with 2% uranyl acetate. ($\times 250,000$.)

We consider a plausible sequence of events is first the formation of the 380-Å diameter ring or segment of helix from 6S protein. This structure then serves as a template for the formation of a second ring or segment of helix on the inside. The double ring is stabilised by polycations but could occur naturally in small amounts and is possibly the disk first described by Borisy *et al.*¹¹. Polymerisation proceeds by growth of this structure to give a short segment of duplex tubule. This short segment then acts as a template for microtubule polymerisation, the microtubule growing from the inner ring. In support of this model, it has been shown that 6S tubulin which does not normally polymerise by itself, will assemble onto the inner wall of a short length of duplex². Also double rings induced by low levels of protamine are incorporated into normal microtubules on polymerisation.

Further studies are in progress to test this model and to determine the relationship between the surface lattices of the various tubule forms.

Table 1 Diameters of the ring forms of tubulin

Type of ring	Conditions	Diameters (Å)*			
		Inner ring		Outer ring	
		Inner	Outer	Inner	Outer
Double ring	Tubulin + protamine at 4 °C	120	250	250	380
Double ring	Tubules + protamine cooled to 4 °C	120	250	250	380
Single rings	Tubules + protamine cooled to 4 °C	—	—	250	380
Single rings	Tubulin 4 °C	—	—	250	380

* Range of diameter measurements $\pm 20\%$.

We thank E. Fricker for technical assistance and Professor E. W. Taylor for helpful discussion.

An outer component of microtubules

I HAVE described (ref. 1 and O.B., unpublished) a method by which microtubules from blood platelets or brain may be isolated in an intact form. They are preserved in a medium containing glycerol and dimethyl sulphoxide and can be collected in large amounts by differential centrifugation. This procedure differs from the usual methods of isolation which begin with unpolymerised tubulin, the protein of which microtubules are comprised^{2,3}, and has the advantage that structures associated with them in the cell are retained (O.B., unpublished). In the electron microscope these appear as a coating around the microtubule wall which is usually of an ill-defined amorphous nature (Fig. 1b).

Occasionally the microtubules show a distinctive structure of regular morphology (Fig. 1a). This is seen in negatively-stained preparations as a thickening of the microtubule wall, of limited extent longitudinally, in which the outer diameter is increased to 360-390 Å, but the inner lumen remains at 120-130 Å (Fig. 1a). The outer component often appears as stacked disks with a periodicity of 50 Å and inclined at an angle of 75° to the long axis, but sometimes a looser structure seems to be wound around the microtubule.

I found that a very similar kind of outer component could be induced at will. Treatment with various compounds caused the microtubules to aggregate and on examination in the electron microscope most of them were seen to have thickened walls. The compounds which did this were Alcian blue 8GX (1%), protamine sulphate (0.1 mg ml⁻¹), polylysines (molecular weights 1,000-30,000; 0.1 mg ml⁻¹) and DEAE-dextran (0.4 mg ml⁻¹), (ref. 4), all of which carry multiple positive charges at the pH of the stabilising medium. The outer components they produced were closely similar to those described above and were made of distinct globular subunits about 50 Å in diameter (Fig. 1c). In specimens fixed in glutaraldehyde and tannic acid⁵ and sectioned, the two layers of the wall were clearly visible (Fig. 1d).

Thus some isolated brain microtubules are decorated with a "natural" outer component but decoration can be induced on virtually all microtubules in a preparation by incubation with certain cationic compounds. There is no proof that the natural and the induced outer components are the same, but their ultrastructural appearance is very similar.

Fig. 1 a, Negatively-stained microtubule showing the outer component ($\times 250,000$). A crude preparation of brain microtubules was made in the following way. Cow brains were briefly homogenised in stabilising medium (50% glycerol, 10% dimethyl sulphoxide, 5 mM $MgCl_2$, and 5 mM phosphate buffer, pH 7), at room temperature. The homogenate was centrifuged, first at 12,000g for 20 min and then at 40,000g for 4 h. The final pellet was resuspended in a small volume of stabilising medium and samples were applied to carbon-coated grids. They were stained with 1% uranyl acetate and examined in the electron microscope. b, Longitudinal section of isolated microtubule ($\times 160,000$). The preparation was fixed in a mixture of 2% glutaraldehyde and 4% tannic acid⁵, without post-osmification, and embedded in araldite by standard techniques. c, Protamine-induced decoration of microtubule, negatively stained ($\times 300,000$). Crude preparations of brain microtubules prepared as in a (ref. 1 and O.B., unpublished), were resuspended in stabilising medium containing 0.1 mg ml⁻¹ protamine sulphate. They were incubated for 4-10 h in this medium before examination in the electron microscope. d, Longitudinal section of protamine-treated microtubule ($\times 240,000$). The preparation was fixed in a mixture of 2% glutaraldehyde, and 4% tannic acid as in b.

The outer component may also be formed on purified microtubules. Preparations which have been depolymerised, and polymerised in stabilising medium many times, and which are pure by SDS-gel electrophoresis, still give extensive decoration on treatment with cationic compounds. Similar observations have been made⁶ with microtubules that have been purified in a different way. Because the outer component seems to comprise a major part of the decorated tubules it seems reasonable to suppose that it can only be made of tubulin.

If the extra layer is composed of tubulin then it must be bound in a specific fashion. The subunits of the outer component are regularly placed and prolonged incubation with cationic compounds for up to 1 week does not result in the deposition of additional layers. Also, the sheets of tubulin which may be formed in some conditions⁶ become decorated only on one side, implying that only the outer side of the microtubule wall may be covered in this way.

The ease with which the outer component can be induced, and the fact that it is occasionally seen in freshly isolated microtubules, suggest that it could be present in the living cell. Structures of this precise nature have not been seen

in thin sections of cytoplasm but it may be relevant that microtubules often seem to be surrounded by a halo of low density⁷. This "clear space" from which other cytoplasmic constituents are excluded, has about the same width as the outer component, and it is not impossible that the two are in some way related.

I thank Dr D. Bray for discussions and criticism, and Drs Jacobs, Bennett and Dickens for access to their unpublished results.

Foetal erythropoiesis in human leukaemia

DURING human development changes occur in the red-cell proteins and antigens¹. At birth the predominant haemoglobin (Hb) is Hb F with approximately 20% and less than 1% of the major and minor adult haemoglobin components (Hbs A and A₂) respectively. Hb F at birth is a mixture of two molecular species, one with glycine at position 136 of the γ chain ($\alpha_2\gamma_2^{136\text{Gly}}$) and the other with alanine at this position ($\alpha_2\gamma_2^{136\text{Ala}}$). The γ chains are designated γ and γ respectively and at birth the ratio of γ/γ is approximately 3:1 (ref. 2). Foetal red cells contain low levels of carbonic anhydrase isozymes B and C and react strongly with anti-i antibody but weakly with anti-I. During the first 12 months the level of Hb F falls and it is replaced by Hbs A and A₂. The ratio of γ/γ chains changes to 2:3 in the small amount of Hb F found in adult life³. The red cells lose their reactivity to i antibody and increase their reactivity to I. The carbonic anhydrase isozymes increase to adult levels by the end of the third year⁴. These changes act as markers for the change from foetal to adult erythropoiesis.

There are several examples of the emergence of foetal proteins during neoplastic transformation⁵. Since at least some human leukaemias involve red-cell as well as white-

cell precursors there may be a reversion to a foetal form of erythropoiesis in these disorders. The only condition where there is a marked increase in Hb F production is juvenile chronic myeloid leukaemia (JCML)⁶⁻¹⁰. We described⁷ a child with this disorder in whom there was a gradual increase in the Hb F level and a reduction in the amounts of Hbs A and A₂ and the carbonic anhydrase isozymes B and C over a period of 12 months. Thus as the disease progressed there was a gradual reversion to foetal erythropoiesis. In the study reported here we have confirmed this observation and shown that foetal erythropoiesis occurs occasionally in other forms of leukaemia.

Our subjects were nine infants or young children with JCML; 64 children and adults with acute myeloblastic leukaemia; 10 with erythroleukaemia; 19 with acute lymphoblastic leukaemia; 30 with chronic myeloid leukaemia and 44 with chronic lymphatic leukaemia. Haematological studies, haemoglobin and carbonic anhydrase isozyme analysis by starch gel electrophoresis, and Hb F and A₂ estimations followed previously described methods^{11,12}. The intracellular distribution of Hb F was assessed by acid elution¹³ or fluorescent anti-Hb F-antibody techniques¹⁴. The relative rates of α -, β - and γ -chain production were estimated by ³H-leucine incorporation¹⁵ and the glycine composition of peptides $\gamma 15$ or CB3 was determined as described previously^{2,16,18}.

The results of haemoglobin and red-cell enzyme analysis on the erythrocytes of 10 infants or children, nine with JCML and one with erythroleukaemia, are summarised in Table 1. The ages ranged from 3 months to 5 yr and the clinical and haematological findings were as in previously reported cases of JCML^{6,7}. The Philadelphia chromosome was absent in each case. In all but two cases high levels of Hb F in the 40-80% range were found, and these increased during the evolution of the illness. The Hb F was heterogeneously distributed among the red cells. In two cases where the fluorescent anti-Hb F-antibody technique was used the fluorescent cells constituted 60.3 and 100% of the total whereas the levels of alkali resistant haemoglobin were 30.2 and 69.5% respectively, indicating that a proportion of cells must have contained both Hbs A and F. In the cases with high levels of Hb F the glycine composition of peptides $\gamma 15$ or γCB3 ranged from 0.69 to 0.81; that is, in the range found in normal cord blood samples². In one case (case 8, Table 1) sequential estimations of the relative rates of α -, β - and γ -chain synthesis were obtained (Fig. 1). Initially γ chains made up approximately 45% of the total non- α -chains produced, which correlated well with the initial Hb F level of 38%. In a sample obtained 4 weeks

* This child had 50% Hb F production by ³H-leucine incorporation studies at the time that the peripheral blood showed 32.8% Hb F.

† Obtained from ³H-leucine incorporation data.

Fig. 1 Elution profiles of globin chains separated by CM-cellulose chromatography in a 8 M urea-mercaptoethanol-phosphate buffer system, pH 6.7. Peripheral reticulocytes and nucleated red cells were incubated for 1 h with ^3H -leucine in the conditions indicated in the text. Cells were then washed, lysed and total cell globin was prepared by the acid-acetone method. The globin chains were separated and the radioactivity incorporated into each chain was determined. Profile *a* is taken from a child with erythroleukaemia just after presentation. Profile *b* was prepared from the cells of the same child 28 d later. There is more β chain carrier in *b* because the child was receiving blood transfusions but it is clear there has been almost a total reversion to γ chain synthesis during the evolution of the illness.

later, γ chains constituted about 80% of non- α -chains produced, indicating that shortly before he succumbed he was producing more than 80% Hb F.

The highest levels of Hb F in the infants and children with JCML and erythroleukaemia were associated with a reduction in the levels of Hb A₂ and carbonic anhydrase B and C (Table 1) and in several cases none was detectable. In these cases the starch gel electrophoretic patterns of the red cell lysates were indistinguishable from those of normal newborn infants. Embryonic haemoglobin was not present. In these cases there was an elevation in the i antigen titre but only in one was there a significant fall in the level of I. Case 6 showed in addition to 70% Hb F, about 3% Hb Barts, but family studies indicated that in addition to having JCML he had received an α -thalassaemia gene from his mother. No haematological abnormalities were found in any other family members and the identical twin in case 3 was completely normal.

Cases 9 and 10 did not follow the pattern outlined above. Case 9 survived much longer, had a higher white cell count and his Hb F level rose to only 13%. Case 10, while having a clinical presentation identical in every way to JCML, ran a milder course and did not produce more than 4% Hb F. Peptide $\gamma 15$ prepared from the latter had a glycine composition of 0.56 residues which is in the range found in the small amounts of Hb F present in normal adults³.

Elevated levels of Hb F were observed also in 43 out of 64 patients with acute myeloblastic leukaemia, 7 out of 8 patients with erythroleukaemia, 12 out of 19 with acute lymphoblastic leukaemia, 19 out of 30 with chronic myeloid leukaemia and 15 out of 44 with chronic lymphatic leukaemia. In most cases the level did not exceed 5% of the total haemoglobin and only in three cases were values in the 10–25% range encountered. No consistent alterations in the levels of Hb A₂, carbonic anhydrase isozymes or I antigens were found. The glycine composition of $\gamma 15$ of the Hb F varied widely, as has been noted by others¹⁰. Hb F levels were followed in a group of 17 patients with acute myeloblastic leukaemia for periods ranging from 1 to 15 months. Fifteen of the seventeen developed an increase in the level of Hb F about 60 d after the commencement of treatment at a time when, following bone marrow aplasia due to

chemotherapy, rapid regeneration was taking place. Significantly greater increases of Hb F levels were observed in those achieving a remission. Details of these patients will be reported elsewhere.

The results indicate that in some forms of leukaemia in early childhood there may be an almost total reversion to a foetal form of erythropoiesis. Levels of Hb F may reach those of cord blood. The levels of Hb A₂ and carbonic anhydrases B and C fall to produce an electrophoretic pattern of red-cell proteins identical to that observed in newborns. This pattern of erythropoiesis, found most commonly in JCML, can occur also in erythroleukaemia and it does not occur in every case of JCML. This may, of course, simply reflect the heterogeneity of JCML²⁰. It was not seen in other forms of leukaemia and the slight elevation of Hb F in these disorders is associated in many cases with recovery from bone marrow aplasia caused by chemotherapy. When the reversion to foetal erythropoiesis occurs it provides a marker for the presence of the neoplastic cell line.

Why does erythropoiesis revert to a foetal form during the evolution of some types of leukaemia in early childhood? It is possible that it is another example of the reversion to foetal protein synthesis which occurs with other neoplasms⁵. If this is the case, however, there is no reason why it should occur much more frequently in infancy. Its occurrence at this time suggests that it is related to the normal mechanism of differentiation of red-cell proteins during maturation. Although by the end of the first year most erythrocytes contain mainly Hb A, cell lines persist which produce relatively large quantities of Hb F^{14,21}. Such 'F cells' are produced in adults in relatively constant numbers, suggesting that some stem-cell lines do not undergo the normal switchover from Hb F to Hb A production. It has been suggested that this switch is hormonally controlled^{1,22} and that the 'F cell' population in adults has arisen by chance in stem cells which did not come under its influence. Thus the chances of a leukaemic transformation occurring in a line making predominantly Hb F would be much greater in infancy and therefore the reversion to foetal erythropoiesis should be much commoner at this age. Similarly the chances of it occurring in adults would be extremely small although an occasional case might occur²³. Thus the findings are fully consistent with the idea⁷ that these leukaemias arise in cell lines which have escaped the normal processes of differentiation during development.

We thank Professors R. M. Hardisty and J. W. Stewart, and Drs H. Kay, M. Ali, J. W. Partridge, W. R. McWhirter, J. Martindale, E. N. Thompson and J. Martin for referring cases. The work was supported by the Medical Research Council, Leukaemia Research Fund and the North West Cancer Research Fund.

Evidence for Hb Lepore-like hybrid globin β chain genes in mice

We have described structural data for mouse and rabbit embryonic β -like ϵ chains and the conclusions which can be drawn with respect to the evolution of ϵ globin chain genes in both species¹. Here we present evidence for crossover events in the ancestral mouse β and ϵ -type chain genes leading to Hb Lepore-like globin chain genes which are functional in mice of recent evolutionary origin.

BALB/c mice, which we used for this study, have two types of embryonic β -like ϵ chains— $\epsilon\gamma$ and $\epsilon\zeta$ (refs 2–7). Based on the composition of tryptic peptides of the $\epsilon\gamma$ and $\epsilon\zeta$ chains,

the tentative sequence of both chains was established using the adult mouse β chains as a reference^{2,5,8,9}. BALB/c mice have two linked genes for the adult β chains, which control the synthesis of the β major and minor globin chains, respectively. The two chains differ at six positions (Nos 9, 16, 20, 58, 72 and 76)⁸.

$\epsilon\gamma$ and β minor chains are closely related since they are identical at four of the six positions at which β major and minor are different. The other two positions are different in $\epsilon\gamma$ from both β major and β minor^{1,2}. Therefore the β minor chain was used for comparison of the structure of the ϵ and β chains. $\epsilon\zeta$ and $\epsilon\gamma$ chains are unrelated apart from their β -like character¹. A comparison of the $\epsilon\gamma$ and β minor chains with respect to the sites of amino acid substitutions shows that most substitutions are located at the amino and also some at the carboxy-terminal ends of the $\epsilon\gamma$ chain, whereas the central part of the chain is almost identical to the β minor chain (Fig. 1).

Rather the reverse is true for the $\epsilon\zeta$ and β minor chains. Here the substitutions are concentrated at the centre of the $\epsilon\zeta$ chain whereas both the amino and carboxy terminal ends look very similar to the β minor chain. Since some peptide composition data of both ends of the ζ chain are, however, still missing, the situation is not as clear as for the $\epsilon\gamma$ chain. The presence of an amino terminal peptide though, which is identical to the adult β -chain peptide composition, leads us to predict close resemblance of the amino terminal part of the $\epsilon\zeta$ chain and of the β minor chain (Fig. 1).

The reciprocal nature of the two ϵ chains as compared with the adult β chains as shown in Fig. 1, suggests that either the β -chain genes or the ϵ -chain genes arose by a crossover event between non-identical genes. Either a single or a double crossover could explain our data. The double crossover interpreta-

Fig. 1 Unequal distribution of amino acid substitutions is found in the embryonic $\epsilon\gamma$ and $\epsilon\zeta$ chains of the mouse as compared with the adult β minor chain. This suggests an origin of either adult β -type or embryonic ϵ type chains by crossover mechanisms, as

Fig. 2 Crossover models which may account for the presence of Hb Lepore-like hybrid globin β or ϵ -chain genes in mice. Two theoretical possibilities can be assumed for the distribution of amino acid substitutions as shown in Fig. 1. (1) Two ancestral genes, that is the ancestral ϵy and ϵz -chain gene form one new gene, the β minor chain gene. (2) Two ancestral genes that is the ancestral ϵ and β -chain gene undergo a crossover event thus creating two new genes, the ϵy and ϵz -chain genes. In principle two models can account for the observed phenomenon of Hb Lepore-like hybrid globin chains. First, the model of misalignment and unequal crossover of closely related genes, which is normally used for the explanation of Lepore haemoglobins. Second, a crossover mechanism involving identical and non-identical genes arranged in parallel on one chromosome. A model of parallel arranged DNA double strands located within one chromosome has for example been proposed by Smithies for the genes of immunoglobulin chains¹¹. The first crossover model of misalignment and unequal crossover only applies to hypothesis (1), that is, two ancestral genes form one new gene at least under the premise of one temporal event. Otherwise one has to assume additional processes of genetic segregation and recombination first separating and then bringing together again the two newly formed genes. The second crossover model involving genes arranged in parallel would account for hypothesis (2), namely two ancestral genes create two new genes, especially under the additional assumption of one single temporal step.

tion would have to be supported by more structural data, mainly on the ϵz chain.

Two main mechanisms are considered here to interpret the crossover origin of mouse β or ϵ -chain genes. The first mechanism would involve unequal Lepore-type crossing over between related non-allelic genes¹⁰, the second would involve reciprocal crossing over between allelic non-identical but closely related genes arranged in parallel on the same chromosome¹¹ (Fig. 2).

We made use of minimal assumptions for explanation of the data. A single temporal event using the generally accepted colinearity of all genes would be the easiest interpretation. If one accepts one single meiotic crossover event to account for the structure of all three β -like genes, ϵy , ϵz and β minor, then the most likely origin would be explained by the Lepore hypothesis (Fig. 2). We assume that the ϵy -chain gene is the ancestral ϵ -chain gene, since ϵy is the only ϵ chain which combines with the embryonic α -type chain χ to form haemoglobin E_1 . The ϵz chain apparently only combines with the adult α chain^{2,3}. Then the ϵz chain might have been the ancestral adult β -type gene. An unequal crossing over (Fig. 2) between these two genes could have generated the adult β gene (anti-Lepore) which was closer to β minor than to β major. A further independent duplication of β minor would then have been the basis for the evolution of an independent β major gene.

This Lepore hypothesis has to be modified if a double crossover would have to be assumed to account for the reciprocal nature of three pieces of the ϵy and ϵz -chains as compared with the β chain (Fig. 1). A prerequisite for this model would be that the ϵz -chain gene was duplicated before the double crossover event. After the double crossover, the β -chain gene would then be between the two ϵ -type genes. This would naturally have consequences for the regulation of coordinated expression of both ϵ -chain genes.

The hypothesis of parallel not colinear genes, if extended to the β -globin loci, would not present any difficulties in the creation of the ϵy , ϵz and β -chain genes, either in meiotic or in other germ line cells. No difficulty would arise for single or double crossovers. No loss or gain of genetic material would occur (Fig. 2). In this model, the β -chain genes do not need to be the result of a crossover between ϵy and ϵz -chain genes. A reciprocal crossover between an ancestral β and ϵ -chain gene could have formed the ϵy and ϵz -chain genes (Fig. 2). The hypothesis just described and the hypothesis of unequal crossover for the origin of Lepore-type globin chains can be checked in patients with Lepore haemoglobin, especially in the homozygous state. The data for one homozygous individual with Hb Lepore Boston¹⁰, who shows no detectable amounts of anti-Lepore globin seem to favour the unequal crossover model.

Fig. 3 Hypothetical arrangement of α and β -type chain genes of BALB/cJ mice on chromosome 11 and 7, respectively. The location of adult α and β -chain genes on their respective chromosomes is known, as is the tight coupling of ϵy and adult β -chain genes. From our crossover hypothesis involving ϵy , ϵz and adult β -chain genes, a coupling of all β and ϵ -chain genes seems to be likely as well as the location of adult β -chain genes between embryonic β chain genes. The information on location and coupling of α -type chain genes was included for the sake of completeness¹⁵. The assumption that the χ chain gene is linked to the adult α globin chain genes is based on structural homology to the adult α chains and also on functional aspects such as mutual replacement of χ and α chains during ontogenesis¹⁶.

Lepore-type β chain has been reported in a species of mouse (*Mus musculus caroli*)¹². Therefore it seems possible that crossover events have been important in the evolution of murine β -chain genes.

In rabbits as in mice, evidence has been obtained for multiple embryonic β -type ϵ chains¹. These chains look much more similar to each other and the distribution of amino acid substitutions compared with the adult β chains of rabbits seems more even than in mice. Therefore we assume that no crossover was involved in the generation of the β -type genes in the rabbit.

The likelihood that either the existing β -chain genes of BALB/c mice or possibly both ϵ -chain genes arose by recombination events suggests that both ϵ -chain genes are closely linked with the β -chain loci (Fig. 3). Linkage of the β minor and β major chain genes^{12,13} and of both to ϵy ^{4,7} on chromosome 7¹⁴ has been shown before.

Embryonic ϵ chains of mice and rabbits

THE existence of an embryonic α -type globin chain (χ or ζ) in early embryos of mice and rabbits has been described¹⁻³. A similar ζ chain can be found in humans^{4,5}. Here we present data on the structure of the embryonic β -type ϵ chains of mice and rabbits. In mice, three embryonic haemoglobins, Hb EI, EII and EIII have been described. These haemoglobins consist of four globin chains, namely the embryonic χ , ϵ and ϵ chains and the adult α chain^{3,6-8}. Hb EI has the structure $\chi_2 \epsilon_2$, Hb EII is $\alpha_2 \epsilon_2$ and Hb EIII is $\alpha_2 \epsilon_2$. The χ chain is an embryonic α -type chain^{1,2}. We find six haemoglobin fractions in nucleated embryonic erythrocytes of the rabbit. Three of the haemoglobins (Hb EI-EIII) do not contain α , but χ chains like Hb EI of the mouse; the other three (Hb LI-III) are similar to mouse Hb EII and EIII¹.

All non- α -type embryonic globin chains of both species are β -type ϵ chains. We find less structural similarity between the ϵ chains of different species than between the β and ϵ chains of the same species. This indicates, in contrast to the embryonic χ chains, that ϵ chains diverged by independent evolution from the ancestral β chains of mice and rabbits.

The ϵ chains of 12-13-d-old embryos of BALB/c mice and of 14-d-old embryonic New Zealand white rabbits were digested by trypsin, and the tryptic peptides were separated by the fingerprinting method. The amino acid composition of the tryptic peptides is shown in Table 1. They were compared with the β chain sequences of mouse (β major and β minor)^{9,10}

and rabbit¹¹⁻¹³. According to the principle of least dissimilarity, the best correspondence was obtained using the β chains of each species as a reference (Fig. 1). The ϵ chain which has erroneously been called ϵ chain previously¹, shows a closer overall homology to the β minor than to the β major chain. In addition, in 4 out of 6 positions, that is in positions 16, 58, 72 and 76, in which the β major and minor chains are different, the ϵ and β minor chains are identical. The other two positions are different from both β major and minor chains. For the ϵ chain, similar conclusions concerning the relationship to either of the two adult β chains are not yet possible because of a lack of data.

In the case of the rabbit, different chromatographic fractions of ϵ chain material have been analysed separately by the fingerprint method. The fractions were, however, not resolved sufficiently for conclusions to be drawn as to how many rabbit ϵ chains are present. All the data were therefore pooled (Table 1, Fig. 1). These peptide compositions were compared with the adult globin chains of rabbits. The closest homology was found using the rabbit β chain as a reference as shown in Fig. 1. The homologised sequence shows close similarity to the adult β chain. At several positions, indicated by brackets, two or three different amino acids had to be placed either because peptides with very similar compositions were found at different spots of the fingerprint or because one peptide showed non-integral values for two different amino acids. This proves the presence of more than one rabbit ϵ chain. The degree of homology of rabbit ϵ and rabbit β is similar to mouse ϵ and β chains.

To get an impression whether a common evolutionary origin of rabbit and mouse chains could be supported by our data, we compared the individual peptide compositions of mouse and rabbit β chains⁹⁻¹³ with the corresponding peptides of the ϵ chains (Table 1, Fig. 1). For comparison, we used the mouse β minor chain as reference chain because of close structural relationship to one murine embryonic ϵ chain, namely the ϵ chain. In the case of the rabbit, the β chain sequence, as reported by Braunitzer *et al.*¹¹ was taken as reference because it looked somewhat closer to the embryonic ϵ chains of rabbits (positions 52 and 56, Fig. 1) than the allelic sequence^{12,13}. Since we used peptide compositions for comparison, even in the case of established sequences, minimal

Fig. 1 Sequence homology of mouse and rabbit ϵ chains as compared with the corresponding adult β chains. The ϵ chain peptide in position 91-95 was taken from Gilman¹⁴. Gilman's sequence data in addition to our peptide data were used for positions 1-30 of the ϵ chain¹⁴. In the case of the rabbit, two or three different amino acids had to be placed at the same positions as indicated by brackets. This proves the presence of more than one rabbit ϵ chain. Serine and glycine have been found in addition in the rabbit ϵ chain peptide homologised to the adult β T1 peptide. It seems possible that both residues are linked to the N terminal end of the rabbit ϵ chain(s), as has been found for a minor fraction of adult rabbit α chain, for the embryonic rabbit α chain²⁰ and for the embryonic rabbit α chain²¹.

differences were determined for all chains. For the calculation we omitted those peptides for which the homology was doubtful. We therefore used for comparison the following homologised stretches: positions 41–82, 96–104 and 121–146 (Fig. 1). In the case of the rabbit for positions 41–59, only the corresponding well fitting peptide was included in the comparison

(Table 1). The $\epsilon\gamma_2$ chain of BALB/c mice has probably asparagine or some unknown residue at position 77, whereas the $\epsilon\gamma_1$ chain may have either lysine or arginine¹⁴. From our data, the presence of asparagine can be excluded (Fig. 1). Of a stretch of peptides totalling 77 amino acids we find the closest homology between mouse β and $\epsilon\gamma$ (3/77 difference) β and $\epsilon\gamma$

The embryonic ϵ globin chains of mouse and rabbit were separated^{1,2}. The embryonic ϵ chains were digested with trypsin and after separation of the tryptic peptides by fingerprinting, the amino acid composition analysis was carried out^{1,2}. Line 1 indicates the residue numbers that were homologised to known β chain sequences. No peptide characteristic of adult β chains have been found.

© Presumably N terminal, partly destroyed.

Values in brackets are estimates because of difficulties with the chromatographic separation or integration.

(10/77) and $\epsilon\gamma$ and $\epsilon\zeta$ (12/77). Almost equally distant seem to be rabbit β and rabbit ϵ (13–14/77) and rabbit ϵ as compared with mouse $\epsilon\gamma$ (14–16/77) and $\epsilon\zeta$ (16–18/77).

In summary, our structural data on embryonic globin chains of mammals show the following characteristic features: in all vertebrate species which have been studied^{2–4,5,7}, there are very early embryonic haemoglobins which contain neither α nor β , but β -like ϵ and α -like χ chains. The χ chain is completely replaced during later yolk sac embryogenesis by the adult α chain. The structure of the χ chain of different species (mouse, rabbit^{1,2}, man^{4,5}) seems to be closely related. No obvious homology apart from their β -like character could be detected for the embryonic ϵ chains of mice and rabbits. Surprisingly, $\epsilon\zeta$ and $\epsilon\gamma$ seem to be more different from each other than from the adult mouse β chain. This might be a consequence of a recent crossover event leading to the β and ϵ chain genes in mice¹⁵. The scarce data on the human ϵ chain¹⁶ do not permit a definitive answer. The human data (ref. 17 and A. Yoshida, personal communication) seem, however, to confirm our impression that mammalian ϵ chains are not very far removed from β chains in contrast to χ and α chains. This failure to find common similarities of the different chains suggests that ϵ or β chains have evolved separately in closely related species such as rabbits and mice, or that ϵ and β chain continuously coevolve¹⁵.

The evolutionary stability of embryonic χ chains and the probably independent evolution of different ϵ chains as well as their close similarity to the β chains suggests that the distinctive functional features of embryonic haemoglobins are due mainly to the χ chains¹⁸. The χ chains may therefore contribute essentially to the high oxygen affinity of embryonic mouse haemoglobins¹⁹.

Predicted distribution of NAD domain among glycolytic enzymes

X-RAY crystallographic studies have indicated that four dehydrogenases^{1–4}, including lactate¹ and glyceraldehyde phosphate⁴ dehydrogenase, contain a central parallel β sheet consisting of six strands flanked by four α helices. This supersecondary structure⁵ is called the dinucleotide fold or nicotina-

mid adenine dinucleotide (NAD) domain since it forms an NAD-binding site at the C terminus of the β sheet. The dinucleotide fold can be considered as two roughly identical mononucleotide domains each containing about 60 residues arranged in an alternating $\beta\alpha\beta\alpha$ sequence and related by an approximate twofold axis⁵. The aromatic specificity site of subtilisin^{6,7} and the flavin-binding site of flavodoxin^{8,9} seem⁵ to be formed by a secondary structure very similar to a mononucleotide domain of the dehydrogenases. Crystallographic studies have shown that the structures of phosphoglycerate kinase^{10,11}, hexokinase¹², adenylate kinase¹³, phosphoglycerate mutase¹⁴ and triosephosphate isomerase¹⁵ also contain β sheets containing at least five strands flanked by at least three α helices. The nucleoside phosphate or, in the case of the mutase and isomerase, the sugar phosphate-binding site for each of these enzymes is either known^{10–12}, or strongly suspected^{13–15} to be located at the C terminus of the β sheet. Differences occur, however, in some of these supersecondary structures relative to the NAD domain of the dehydrogenase family as regards the direction of the β strands¹², the location of the binding site relative to the plane of the β sheet¹², and most significantly, the sequential order or connectivity of the individual strands in the β sheet^{12–14}. Whether these related supersecondary structures represent convergent^{5,12} or divergent evolutionary processes^{4,16}, or both¹⁷, is a topic of active debate.

We have demonstrated¹⁸ that blue dextran–Sephacryl chromatographic columns seem to function as affinity columns specific for proteins whose nucleoside phosphate-binding sites are constructed by the NAD domain or by a supersecondary structure having a connectivity similar to that of the NAD domain and whose apolar pocket is located above the β sheet. If so, such affinity chromatography can be used to predict the presence of such supersecondary structures in proteins whose high resolution crystallographic structures have not been

Fig. 1 Elution profile of aldolase from a blue dextran–Sephacryl affinity column. About 100 μ l solution of aldolase containing about 100 μ g protein in 10 mM Tris-HCl buffer, pH 7.5, was applied at zero effluent volume to a 1 ml affinity column equilibrated with the same buffer. The column was then washed with five 1 ml aliquots of the buffer and with five aliquots containing either 10 mM fructose-1,6-diphosphate (○), or 100 mM NaCl (●). Enzymic activity of aliquots of effluent fractions was measured using the standard coupled spectrophotometric assay procedure.

Fig. 2 Spectral measurements of aldolase-dye complexes. *a*, Difference spectral titration of aldolase with dye. Identical aliquots of a concentrated solution of Cibacron blue F3GA dye were added to the same volumes of a 23 μ M aldolase subunit solution in 10 mM Tris-HCl buffer, pH 7.5, and to the solvent. *b*, Difference spectral titration of aldolase-dye complex with ligands. Increasing concentrations of fructose-1,6-diphosphate (●) or NaCl (△) were added stepwise to a 23 μ M aldolase subunit solution in 10 mM Tris-HCl buffer, pH 7.5, containing 77 μ M dye and to a 77- μ M dye solution in the same solvent. Extinction values are in terms of protein subunit concentration corrected for dilution.

reported. Since crystallographic studies have clearly demonstrated that several glycolytic enzymes contain the NAD domain, we have utilised affinity chromatography to predict the distribution of the NAD domain or close analogues thereof among all the enzymes in the glycolytic pathway.

Results of such a chromatographic survey, summarised in Table 1, indicate that phosphorylase *a*, phosphofructokinase, fructose diphosphatase, aldolase and pyruvate kinase specifically bind to the blue dextran-Sepharose chromatographic columns at pH 7.5 and is eluted by a concentration of its specific phosphorylated substrate or effector at least an order of magnitude less than the concentration of the nonspecific ligand, NaCl. A typical elution profile is illustrated in Fig. 1. Although enolase also binds to blue dextran columns at pH 7.5, it is eluted equally well by solutions containing the same ionic strength of specific ligands, phosphoenolpyruvate or 2-phos-

phoglycerate, or the nonspecific ligand, NaCl. Such behaviour is characteristic of ion-exchange chromatography and is not indicative of a specific interaction. By contrast, hexokinase, either in the presence or absence of 10 mM glucose, phosphoglucose mutase, triosephosphate isomerase, and phosphoglucose isomerase do not bind to the chromatographic columns at pH 7.5.

Conclusions as to the formation of specific enzyme-immobilised dye complexes are supported by difference spectral measurements using the free dye of blue dextran, Cibacron blue F3GA. Complexing of the free dye with lactate dehydrogenase and phosphoglycerate kinase produces difference spectra having positive maxima in the range 660–680 nm, presumably due to insertion of the dye into the hydrophobic pockets of the NAD site formed by the NAD domain¹⁹. The hyperbolic dependence of the difference maximum extinction at 680 nm resulting from addition of the free dye to aldolase (Fig. 2) indicates the formation of a discrete enzyme-dye complex. Since the substrate, fructose-1,6-diphosphate, is much more effective than the nonspecific ligand, NaCl, in diminishing the difference extinction (Fig. 2), it is likely that the free dye specifically complexes with aldolase at its substrate sites. By contrast, the nonspecific ligand, NaCl, is equally effective on an ionic strength basis with the ligands ATP and 2-phosphoglycerate in diminishing the difference extinctions of hexokinase-dye and enolase-dye complexes, respectively, indicating that the dye does not bind to the nucleoside or sugar phosphate-binding sites on these enzymes.

These measurements predict that either the catalytic or effector sites of phosphorylase *a*, phosphofructokinase, fructose diphosphatase, aldolase, and pyruvate kinase are likely to be constructed by supersecondary structures closely resembling the NAD domain. The occurrence of such a large common element within the structures of the majority of the glycolytic enzymes suggest that such enzymes may be derived from a common ancestral protein. The predicted occurrence of a structure similar to the NAD domain, in aldolase is particularly noteworthy as this enzyme has no known nucleoside phosphate substrate or effector.

Table 1 Interactions of glycolytic enzymes with blue dextran-Sepharose affinity columns

Enzyme	Source	Bound	Eluant
Phosphorylase <i>a</i>	RM	Yes	10 mM AMP
Phosphoglucomutase	RM	No	—
Hexokinase	Yeast	No	—
Phosphoglucose isomerase	Yeast	No	—
Phosphofructokinase	<i>Escherichia coli</i>	Yes	0.1 mM ATP
Fructose diphosphatase	RM	Yes	1 mM AMP
Aldolase	RM	Yes	10 mM FDP
Triosephosphate isomerase	RM	No	—
Glyceraldehyde-3-phosphate dehydrogenase	RM	Yes	10 mM NAD
Phosphoglycerate kinase	Yeast	Yes	1 mM ATP or 3-PGA
Phosphoglycerate mutase	RM	Yes	0.5 mM 2,3-PGA
Enolase	RM	Yes	1 mM 2-PGA or PEP
Pyruvate kinase	RM	Yes	10 mM ATP or PEP
Lactate dehydrogenase	RM	Yes	1 mM NADH

Bound, indicates whether up to 0.5 mg of enzyme binds to a blue dextran-Sepharose affinity column having a 1 ml bed volume equilibrated with 10 mM Tris-HCl buffer, pH 7.5. Eluant, indicates concentration of the listed compound added to the equilibrium buffer which elutes the bound enzyme in at least five column bed volumes.

RM, Rabbit muscle; FDP, fructose-1,6-diphosphate; PGA, phosphoglycerate; PEP, phosphoenolpyruvate. All enzymes were commercially available purified proteins except for *E. coli* phosphofructokinase which was purified as described previously¹⁸. Enzymic activity was measured by standard assay procedures.

X-ray diffraction patterns from haemoglobin-free erythrocyte membranes

In a survey¹ of X-ray diffraction patterns from erythrocyte membrane preparations produced by hypotonic lysis within a range of tonicities and pH, we emphasised the lability of the haemoglobin-free membrane preparation which readily degenerated during dehydration to give both lipid and residual membrane (lipoprotein) phases. The lipid was identified with a diffraction periodicity of 5–5.5 nm which was sensitive to temperature changes and which could be eliminated by treatment of the membranes with phospholipase C before dehydration². In electron micrographs of sections prepared from the same samples the lipid phase was identified with regions of very fine layering (4 nm periodicity) scattered irregularly through a mass of closely packed layering of much greater dimension, which undoubtedly represented the condensed erythrocyte ghosts. These closely packed ghosts provided periodicities of 20–30 nm, each period including two apposed thicknesses of membrane which were clearly asymmetrical. The corresponding X-ray diffraction patterns also revealed this higher periodicity. We have since experimented with various conditions which can be used to provide haemoglobin-free membranes and have obtained much-improved X-ray diffraction data which confirm and extend our earlier conclusions.

Stomatoff *et al.*³ carried out X-ray diffraction studies from which they concluded that the hydrated, haemoglobin-free erythrocyte membrane is only 5.5 nm thick and is a symmetrical structure. Blaurock and Lieb, in a comment in the News and Views section of *Nature*⁴, remarked on the similarity of the electron density profile proposed for this membrane and the profile of a bimolecular layer of lipids⁵. We have no doubt that the 5.5-nm periodicity analysed by Stomatoff *et al.* does relate to a lipid phase formed in the haemoglobin-free erythrocyte ghost preparation during partial dehydration, and that they have either failed to record or overlooked the higher periodicities which relate to the membrane structure. We have studied membranes prepared exactly as reported by Stomatoff *et al.* and have found their diffraction and electron microscope characteristics to be essentially similar to those of other haemoglobin-free ghosts prepared in hypotonic conditions.

The accumulated data are being analysed in detail in an attempt to elucidate the molecular changes involved in these phase separations which occur during dehydration or partial dehydration of a wide range of membrane preparations. They will be included in a more extensive publication on this topic. Meanwhile it seems important to

Fig. 1 *a*, Microdensitometer trace of a low angle X-ray diffraction pattern recorded from a haemoglobin-free preparation of erythrocyte ghosts (see text) after partial dehydration. The two principal diffraction bands are identified in terms of the periodicities they represent. *b*, Electron micrograph ($\times 160,000$) from the same erythrocyte membrane preparation, fixed with OsO_4 after partial dehydration, embedded and thin-sectioned. The fine layering on the right is suggested to correlate with the smaller diffraction periodicity and the packing of residual ghosts on the left and below correlates with the large diffraction periodicity.

re-emphasise the significance of this phenomenon in relation to studies of membrane structure by reporting one well-defined example which is particularly relevant to X-ray diffraction studies of haemoglobin-free erythrocyte ghosts.

Figure 1a shows a microdensitometer trace across one of a sequence of low angle X-ray diffraction patterns recorded during the slow dehydration of a sample of haemoglobin-free erythrocyte ghosts which had been prepared (at 0–4 °C) by haemolysis of pig erythrocytes in 20 mosmol bicarbonate buffer, pH 7.0, containing 1 mM EDTA and centrifuged at 200,000g for 3 h. A sample of the wet pellet was enclosed immediately in a chamber maintained at high ($\sim 100\%$) humidity and constant (10 °C) temperature. A sequence of low angle diffraction patterns (limit of resolution 25 nm) was then recorded using a single bent quartz crystal monochromator and a line view of the focus of a rotating anode X-ray generator. Initially

only broad maxima in the region of 6.5 and 10 nm were recorded but as the former intensified and improved in definition an equally intense and well defined reflection was resolved at 2.5 nm. This reduced in successive exposures to about 20 nm and the 6.5-nm periodicity to 5.5 nm in the fully dried sample.

A parallel sample was fixed with osmium tetroxide at an intermediate stage of dehydration (corresponding approximately to the stage represented by Fig. 1a) and prepared for electron microscopy. A representative micrograph is reproduced in Fig. 1b. The bulk of the sample consisted of collapsed erythrocyte ghosts, closely packed to give a periodicity of the order of 30 nm but this was interspersed with small pockets containing material which featured a very fine (~4 nm) periodicity. There is little doubt that the 5.5–6.5-nm periodicity detected by X-ray diffraction relates to this finely layered component which we have previously identified as a lipid phase. The discrepancy in dimension is a consequence of the preparative procedures required for electron microscopy⁶. The residual membranes are responsible for the higher (>20 nm) periodicities. Each membrane features a trilamellar unit with additional dense material at the cytoplasmic face, forming overall an asymmetrical unit which is approximately 10 nm thick in the dried sample. Two such units are apposed in the collapsed ghost.

State of chlorine and potassium in human platelets and red cells

THE behaviour of excitable cells is consistent with most of their potassium and chlorine being ionised. It has been assumed that this state of affairs is also true of other types of cell. With electron microprobe analysis we have found that most chlorine in human platelets and potassium in human platelets and red cells is present not as free ions but as complexes that can be dissolved by lipid solvents. In platelets, chlorine seems to be complexed with a proteolipid. The anaesthetic halothane, in conditions that will provoke deep anaesthesia, interferes with the complexing between chlorine and the proteolipid in platelets, so that much less chlorine is extractable with lipid solvents.

Air-dried and freeze-dried platelets and red cells had a large chlorine emission peak (Fig. 1) from all parts of their cytoplasm. The microprobe has already revealed an unexpectedly large chlorine peak in muscle¹. By comparing the Cl-S peak ratio with the Cl-P peak ratio, we have attempted to estimate whether the chlorine in platelets is in the membranes or in the ground substance of cytoplasm. Although membranes are present throughout the cytoplasm of platelets, some parts contain more membranes than others. It was assumed that regions with a large phosphorus emission peak were rich in membranes containing phospholipids, for the phosphorus emission peak almost disappears when platelets are treated with chloroform-methanol. The only cytoplasmic region that gives a sub-

stantial phosphorus peak after this treatment consists of the dense bodies that contain stored ATP, ADP and inorganic pyrophosphate². The size of the sulphur emission peak was taken to indicate the thickness of cytoplasm under the beam. We found that the Cl-S ratio varies from platelet to platelet (mean 2.27, s.e. 0.07, $n = 37$) but was relatively constant with each platelet. The Cl-P ratio varied more widely (mean 2.76, s.e. 0.15, $n = 37$). Since the standard error of the Cl-S ratio is so much smaller than that of the Cl-P ratio it seems that the chlorine in platelets is in the ground substance of cytoplasm rather than in the membranes. The reason for the variation in Cl-S ratio from platelet to platelet is not clear.

Virtually all the cytoplasmic chlorine was extracted from desiccated, air-dried or freeze-dried platelets by dry 2:1 chloroform-methanol. Extraction was nearly complete after 1 min and was complete after 15 min (Fig. 1). This was the pattern for normal platelets, for those in which secretion of dense bodies had been inhibited by 0.04 mg atropine per

Fig. 1 Emission spectrum from human platelets. The upper spectrum is from the cytoplasm of a normal, air-dried platelet, from a region rich in potassium, the lower from a similar specimen extracted with dry chloroform-methanol. Platelets were prepared from both normal humans and pigs by placing a drop of platelet-rich plasma on carbon-coated copper grids for 10 s and blotting them. They were then either air dried and desiccated for 24 h with silica gel, or immediately freeze dried. For freeze drying the grids were immersed in liquid nitrogen and dried at -60°C in an Edwards tissue dryer Mk 1 for 2 d; they were warmed to room temperature under vacuum. Some grids were extracted for 15 min with 2:1 A R chloroform-methanol prepared from freshly opened bottles and dried with dry Union Carbide molecular sieve 4A (BDH). The specimens were then analysed in an AEI EMMA 4 electron microanalyser equipped with a Kevex Si (Li) energy dispersive detector. A liquid N_2 specimen decontaminator was used throughout this study so that the sulphur peak could be used as standard.

Table 1 Effect of treatment on chloroform-methanol extraction

Treatment applied to living cells	Extractability in chloroform-methanol after drying
Normal pig platelets	All chlorine and potassium extracted
Platelets from pigs anaesthetised with halothane	Varying amounts of chlorine and potassium retained in platelets In many platelets all chlorine and potassium is insoluble
Platelets from pigs stunned electrically at abattoir	Some chlorine is insoluble, nearly half the potassium is insoluble.

ml plasma³, and for those aggregated for 5 min by $2 \mu\text{M}$ ADP at 37°C , before drying. It seems likely that even though removal of water inevitably alters the distribution of charge within a cell, extractability of chlorine by lipid solvents is typical of these cells in life, for the following reasons. First, freeze drying should avoid the creation of high local concentrations of ions that might cause abnormal binding to cell components. No ice crystals were visible by electron microscopy in platelets freeze-dried on carbon-coated grids. Second, various semi-physiological treatments to living platelets influenced the pattern of extractability even after drying (Table 1). The variation in response to halothane was probably due to sequestration of a proportion of the total platelet population in regions where the concentration of halothane was less.

Fig. 2 Emission spectrum from human red cells. The upper spectrum is from a normal, air-dried red cell, the lower from a similar specimen extracted with dry chloroform-methanol.

The chlorine dissolved from platelets by dry 2:1 chloroform-methanol was almost all precipitated from this solution by diethyl ether. This ether precipitate consisted of white fibres, soluble, like the apoprotein of a proteolipid^{4,5} in either dry chloroform-methanol or distilled water. The ability of this complex to exist in either hydrophilic or hydrophobic situations may well be crucial to its functioning in platelets. After storage for a few days at -20°C the dry precipitate lost its solubility in water, and later in chloroform-methanol. The extractability of chlorine from dry platelets by chloroform-methanol also decreased as storage time of dry platelets increased. After prolonged storage no chlorine could be extracted from dry platelets by chloroform-methanol. In aqueous solution the ether precipitate had an absorption shoulder at 280 nm; with silver nitrate solution it gave a thick curdy precipitate shown by the microprobe to contain silver and chlorine. A balance sheet of chlorine present in platelets and recoverable from the proteolipid precipitate is being constructed.

The chlorine in human red cells was almost entirely insoluble in chloroform-methanol (Fig. 2). Red cells provided a useful internal control that demonstrated that platelets do not lose their chlorine through hydration of the chloroform-methanol. Adjacent platelets and red cells on the same grid square lost virtually all or virtually none of their chlorine respectively when extracted with chloroform-methanol.

Potassium had a very uneven distribution in the cytoplasm of platelets. Some regions had three to four times the concentration of other regions. The regions with a high concentration of potassium have not been identified. The potassium of dry platelets and red cells was almost entirely soluble in dry chloroform-methanol (Figs 1 and 2). Since this was as true for freeze-dried cells as for air-dried, this cannot have happened through abnormal binding due to high intracellular concentrations produced by air drying.

Much of the potassium extracted by chloroform-methanol was precipitated by ether as a fibrous precipitate soluble in both chloroform-methanol and in distilled water. It seems possible that, as in the case of chlorine in platelets, complexes with proteolipids influence the ionisation of potassium in red cells. This is thus a special case of the theory that cytoplasmic proteins adsorb water and metal ions cooperatively⁷. Preliminary studies with other cell types (human leukocytes, pig endothelial cells and rat striated muscle) suggest that the pattern of solubility of their cytoplasmic chlorine and potassium in lipid solvents resembles that of the red cells. The availability of free ions in cells may be controlled through complexing with proteolipids. If this were so then the observed action of halothane on platelets may be related to its anaesthetic action on excitable cells.

We thank Mr J. P. Emmines for technical assistance, Dr D'A Kok for normal human blood and Drs M. Pye and D. de Bono for pig blood. R.J.S. is supported by the Leukaemia Research Fund. Funds for the EMMA 4 instrumentation were provided by the Science Research Council.

matters arising

Interpretation of apparent ages in Minnesota

GOLDICH and Hedge¹ have reported ages from the Montevideo gneiss in south-western Minnesota of $3,950 \pm 70$ Myr. They also obtained an age of 3,800 Myr by including a sample from the Morton Gneiss (54 km distant). The results apparently indicate that those rocks are at least as old as any yet found on Earth. Our work in that area² does not, however, support those results. Evidence that a Rb-Sr age has been inadequately measured is provided by the failure of some of the samples to lie on an isochron (within experimental error). That occurs with two of the samples measured by Goldich and Hedge¹. In addition, the least squares fit for all of their data gave an age of $3,688 \pm 310$ Myr (2σ) and the best fit for their Montevideo Gneiss samples is $3,460 \pm 370$ Myr (2σ). In conditions of partial re-equilibration it is possible to obtain apparent ages which could be either too old or too young.

To understand better the extent of Sr mobilisation during the metamorphism of this area, we have sampled the Montevideo Gneiss on two scales: multiple samples from individual blocks about 2 m in size, and on the scale of kilometres, as was done by Goldich and Hedge¹. Analytical data are given in Table 1. The samples collected from the individual blocks may reveal local, partial or complete equilibration at the time of metamorphism. If that is so, there is no reason to believe that widely separated samples represent anything more than individual points on different local metamorphic isochrons, and their colinearity may well be fortuitous, and the age so indicated erroneous.

The Montevideo Gneiss comprises bands of grey rock interlayered with red bands. Goldich sampled the grey portions to avoid contamination with the younger red material. According to Goldich and Hedge the 3,800 Myr isochron indicates that the grey rock remained a closed system during the emplacement of the red phase (Goldich, personal communication). We do not find that to be the case. The effect of local re-equilibration is seen most clearly in the data from block MV-102 (Fig. 1a). Regardless of any original difference in age, both the grey and red bands lie on a single isochron at $2,472 \pm 44$ Myr (2σ); the high initial ratio, 0.7121 ± 0.0008 (2σ) strongly suggests that it represents a time of meta-

Fig. 1a Rb-Sr isochron for the red and dark bands of block MV-102 from the Montevideo Gneiss (age, $2,472 \pm 22$ Myr (1σ); initial ratio, 0.7121 ± 0.0004 (1σ). Error: 1% in $^{87}\text{Rb}/^{86}\text{Sr}$; 0.0001 (1σ) for $^{87}\text{Sr}/^{86}\text{Sr}$. b, Block MV-100 isochron with red and dark phases from the Montevideo Gneiss near Carlton Lake (age, $2,727 \pm 199$ Myr. (1σ); initial ratio, 0.711 ± 0.004 . c, Best fit isochron for samples from the locality KA-209 of Goldich¹, including the red and the dark phases (age, $3,111 \pm 202$ Myr; initial ratio, 0.706 ± 0.001 . morphic re-equilibration, rather than of original crystallisation.

To a lesser but still considerable extent the effects of local mobilisation are observed at the other two sites we have sampled (MV-100 and KA-209). We believe that samples from those localities were among those used by Goldich and Hedge in constructing their 'isochron'. Locality KA-209, the designation of the most radiogenic point obtained by Goldich and Hedge, is presumably the locality previously designated that by Goldich, Hedge, and Stern³.

Results from block MV-100 are given in Fig. 1b. In this case the range of

Rb-Sr ratios is not large; however, all of the points lie well to the right of the isochron of Goldich and Hedge and, again, the dark and red rocks no longer preserve any record of possible original age differences. Samples from locality KA-209 (Fig. 1c) were not from a single block, but from an area about 20 m in dimension. Perhaps for that reason, because of local variability in the extent of remobilisation, the samples were not completely re-equilibrated at 2,500 Myr. Both the dark and red phases scatter along a $\sim 3,100$ Myr 'errorchron'⁴. Our sampling reveals no tendency for either the dark or red phases from any of these

localities, taken individually or in combination, to be aligned on a 3,800 Myr isochron. Rather, they seem to be ancient rocks of uncertain age (probably > 3,100 Myr), which, locally, have been partially or nearly completely reset during a phase of metamorphism about 2,500 Myr BP. Ages in the vicinity of 3,300 Myr BP are suggested by zircon data^{2,3}.

GOLDICH AND HEDGE REPLY: We wish to correct a procedural error in our original article¹ relating to the age of $3,950 \pm 70$ Myr (2σ) with an initial ratio of 0.698 ± 0.004 . The use of 2σ is not proper because of the small number (5) of samples. The recalculated results give an age of $3,950 \pm 130$ Myr with an initial ratio of 0.698 ± 0.002 (95% confidence level). We included "sample 339 from the Morton Gneiss as a guide to the initial ratio of 0.700 and an age of 3,800 Myr."

Rb-Sr analyses of the tonalitic phase of the Morton Gneiss of Lund² have progressed to a 7-point isochron with an apparent age of $3,630 \pm 60$ Myr with an initial ratio of 0.6994 ± 0.0004 (95% confidence level). The data will be published in the near future. Additional work is also in progress in the Granite Falls

area. The fact that two points do not lie on the isochron in our original diagram means that those samples have had somewhat different histories and is not evidence that an age has not been measured. In this regard some of Farhat and Wetherill's data are relevant.

Four samples of the 'red phase' from locality KA-209 and three samples from locality MV-100, together with three unpublished analyses by Hedge of the more massive granitic phase, define an isochron (Fig. 1) with an apparent age of $3,000 \pm 90$ Myr with an initial ratio of 0.7065 ± 0.0016 (95% confidence level). Three different localities are represented, but in spite of Farhat and Wetherill's reasoning we feel that the linearity is more than simply fortuitous. The 3,000-Myr age in the Granite Falls area was noted in our original paper¹. It may represent a regional high-grade metamorphic event that affected both gneissic and more massive phases of the Montevideo Gneiss, but it is possible, if not more likely, that it dates the time of intrusion of granitic magma in a foliated terrain of tonalitic to granodioritic rocks. Both phases were later affected by at least two younger events. We are dealing with a complex geological history in which the effects of interaction between magma and country rock as well as regional metamorphism must be considered.

The 2,470 Myr isochron (MV-102) also is useful, and is not unexpected as we have similar unpublished data. The Montevideo Gneiss has undergone intensive shearing and hydrothermal alteration, and some of the apparent ages in the range 1,850–2,500 Myr BP (ref. 4) may be related to this type of activity. We suggest that Farhat and Wetherill have not considered the variety and complexity of the geological processes and that neither the 3,800 Myr isochron¹ nor the 3,000 Myr isochron are necessarily 'fallacious isochrons'⁵.

Inhibition of Na, K-activated ATPase and release of neurotransmitters

GILBERT *et al.*¹ have raised the question whether a change in the local environment of the neuronal membrane Na, K-activated ATPase (ATPase) could result in a change both in its activity and in its conformation such that an increase in exocytosis occurs; in this manner the activity of ATPase in the

nerve terminals and the regulation of neurotransmitter release would be coupled. It has also been suggested that the physiological release of acetylcholine from guinea pig ileum and rat brain cortical slices may be mediated through inhibition of the neuronal membrane ATPase^{2,3}. We have shown that several procedures which are known to inhibit ATPase cause a marked release of noradrenaline from sympathetic nerve terminals of the cat spleen^{4,5}. Since physiological release of neurotransmitters is dependent on calcium entry into the neuron^{6,7} the question arises whether calcium entering the neurone during depolarisation may inhibit ATPase⁸, so that inhibition of ATPase is the underlying mechanism in the physiological release of neurotransmitters.

It is generally believed that physiological release of noradrenaline from sympathetic nerve terminals occurs by exocytosis. This belief is mainly based on the demonstration of proportional release of noradrenaline and the soluble form of the vesicular enzyme dopamine- β -hydroxylase (DBH) in response to stimulation of sympathetic nerves⁹. If the physiological release of noradrenaline is mediated through ATPase inhibition, then procedures leading to a decrease in ATPase activity should cause a proportional release of noradrenaline and DBH. We demonstrated however that one such procedure, namely sodium deprivation, caused a pronounced release of noradrenaline (800 ± 85 ng g⁻¹, $n=3$) from cat spleen slices yet the release of DBH over the background level was barely detectable¹⁰. This result indicates that at least noradrenaline release from sympathetic nerves by sodium deprivation is due to some mechanism other than exocytosis. If the mechanism of release of noradrenaline by sodium depletion is presumed to be due to inhibition of ATPase⁴, then physiological release of neurotransmitters by exocytosis is not simply the result of ATPase inhibition.

reviews

AN author with the technical knowledge and presentational skill of John Maddox needs no introduction or recommendation to readers in the field of energy. His experience as science correspondent of the *Guardian*, Editor of *Nature* (1966–73), and his frequent contributions to radio and television on topical scientific subjects fit him well to project himself 'beyond the energy crisis'. Those who have read his earlier work, particularly *The Doomsday Syndrome*, will want to get hold of this new one*.

There are no visual illustrations or tables in the book but the words are well chosen and the sentences crisp and vivid. He prepares a launching pad for the main verbal discussion of energy market forces, success by the OPEC oil cartel and the problems of heavily oil-dependent customers by considering the "history" of energy supply and use.

In describing the patterns of energy consumption Maddox ensures that the reader need not be technical to enjoy and understand the presentation. He explains the units for energy and power clearly for the layman and is constantly bringing in something of interest for the specialist—for example, that the Second Law of Thermodynamics was the test advocated by C. P. Snow for the literacy of non-scientists. Both would of course know now about the heavy dependence of many countries on imported oil, but perhaps not the detail of it for specific countries; nor might they have fully appreciated the financial problems arising for many industrial and developing countries alike whose development processes are postponed when oil supply is restricted.

Maddox the realist comes through as he assesses the coal, oil, gas and nuclear energy supply prospects (the new lodes to work) and weighs their advantages and disadvantages. Why not have the best of both worlds and rely instead on new sources of energy free from hazards—solar, geothermal, thermonuclear? The short answer—serious doubts about the cost and the feasibility of meeting growing demand for energy by these means. He concludes that the contribution they will make to future energy supplies will be negligible for several decades and may always be small.

When discussing the policies fol-

UKAEA

Rising to the occasion

lowed by the energy hungry, advanced or industrial countries Maddox asks why their governments should have been so naive in failing to follow the precepts of elementary economic textbooks, and concludes that they simply did not look far enough ahead to protect their interests against an oil supply cartel or shortage. He criticises their foolishness in not having seen the signs, for example, from events in Iran during the Moussadeg period 1952–54, but he is a bit unfair to say that the British decision to initiate the 1955 nuclear power programme because of the fear for the security of oil supplies was wrong. With hindsight it should have been doubled again by 1960 while sticking with the Magnox system, with which design and construction experience had been gained; and again in 1965 with only one Advanced Gas-cooled Reactor Power Station innovation being allowed as a lead into the commercial field. The early Arab-Israeli wars were a sufficient pointer to the necessary British energy strategy.

Variation in tempo is a feature of the book, especially as the international monetary problems of today are left behind. The cost of and benefit from insulating a house in Britain enters the discussion. In suggesting that it could be much better to import oil, even at OPEC prices, than to improve the efficiency of energy consumption

Maddox fails to put a value on independence from a cartel which might act again for purely political reasons.

Looking beyond the energy crisis to the coming decades the realist Maddox again emerges, seeing it as unthinkable that Britain would consider the unemployment that a sharp decrease in energy consumption would cause more acceptable than the small risks of reactor accidents; just as developing countries would not settle for slower economic growth or reduced agricultural output for the sake of keeping nuclear power at bay.

Clearly, there is an interesting way ahead, with the possibility that the oil consumers might reduce their oil consumption by 10 to 15% to bring the divergent interests of OPEC members to the surface and/or diversify their energy resource investments, or apply import duties and quotas as a means for encouraging a more equitable, lower price to be set for oil. Clearly, the energy crisis is not over; how can it be when our industrial revolution of more than a century ago is still spreading round the world with a voracious energy appetite. The oil crisis is today, the uranium crisis may be tomorrow; both are seen by Maddox as "merely occasions for the exercise of that blend of courage and realism on which industrial society is founded."

Plant and leaf

Phytochrome and Photomorphogenesis: An Introduction to the Photocontrol of Plant Development. By Harry Smith. Pp. xiii+235. (McGraw-Hill: London and New York, 1975.) £7.95.

THE quotation from Stephen Hales and the coloured frontispiece illustrating light- and dark-grown seedlings are a fitting introduction to the contents of this book. In the nine chapters that follow the author has analysed how light from particular spectral regions is perceived, measured by the plant and translated through modifications of biochemical pathways into a recognisable pattern of growth and differentiation. Apart from relevant discussion of the spectral activity and nature of the receptor for phototropic responses, growth effects dependent on the direction of light (phototropism) or time of exposure to light (photoperiodism) are not within the scope of this book.

Before describing the evidence for the existence of specific photoreceptor molecules the author has included a chapter on the physical properties of light in relation to action spectra and photochemical response with methods for experimental manipulation of light sources. This will be particularly help-

ful to those who are entering this field of photobiology for the first time.

The important experiments leading to the discovery, isolation and identification of a chromoprotein absorbing at red and far-red wavelengths, and the evidence for another receptor absorbing in the blue region of the spectrum, have been carefully culled from the literature, and are dealt with historically and analytically with great clarity. In one chapter the chemical properties of phytochrome are treated in detail, with present views of the likely photo-transformations and conversions of the chromophore-protein complex both *in vitro* and *in vivo*.

The quantitative detection within the plant, the likely localisation within membranes, and the evidence linking developmental responses to different forms of phytochrome *in vivo* is presented in a way that leaves the reader in no doubt of the hard facts as well as the problems and paradoxes.

Major proposals for the mechanism of phytochrome action are discussed on the basis of chemical and biological data. The extensive studies of phytochrome involvement in germination and seedling growth form the subject of two chapters, but here some crispness of presentation is lost amongst the many factual details. The longest chapter is devoted to biochemical changes associated with the phytochrome-mediated photocontrol of development.

The book as a whole is carefully and thoughtfully written and easy to read, its many subtitles providing quick reference from one section to another. As a comprehensive survey of the present state of knowledge in the field, with pointers to areas of future study, this work is valuable for students, teachers and research workers and all who wish to learn about phytochrome in plant growth. An informed interest in photomorphogenesis must surely result for anyone who reads this stimulating book. **Daphne J. Osborne**

The Shoot Apex and Leaf Growth: A Study in Quantitative Biology. By R. F. Williams. Pp. vii+256. (Cambridge University Press: London, March 1975.) £6.50; \$18.95.

THE organisation of leaf primordia at the shoot apex, which in many cases can be described mathematically, is a fundamental and obvious system for studying the concepts of positional information and development of form in plants. It is always surprising to me that the shoot apex has not been exhaustively studied in this respect, compared with the more widely used animal systems. A treatise on the shoot apex and leaf growth is therefore potentially exciting reading to those interested in the development of

form. The bulk of this book, 143 out of 223 pages, is devoted to detailed descriptions, ultimately expressed as three-dimensional scale drawings, of the vegetative growth of a dozen plant species encompassing a wide range of different developmental patterns. The development of the inflorescence of wheat is also described, and the detailed comparison of vegetative and floral apices provides some insight into the control of floral induction. These results are supplemented by a further 22 pages detailing the more complicated aspects of the methods used in these studies. After reading these sections which, in the author's words "many will be content to treat as resource material . . . to check the claims made elsewhere", the potential of the shoot apex as a system for studying the development of form is fully justified. Unfortunately, very little is concluded from this wealth of information, and the author in fact suggests that further "comparative, quantitative morphology of these objects will certainly yield valuable insights in its own right". Perhaps, however, this is the time to put the microtome back on the shelf, and try to formulate the type of "insight" on which this type of analysis may throw some light.

The major conclusion drawn from these studies is the importance of physical constraint on the growth rate of the apex and component parts. Although, with hindsight, this is perhaps an expected dependence, it is well supported by the developmental data from the different types of apex, and tested quite convincingly in a series of experiments involving tiller formation in wheat. The claim that physical constraint may play a part in the genesis of form is less convincing. Whether the physical constraint at the shoot apex is the cause or the result of the phyllotaxis and leaf shape is a moot point. It is disappointing that no attempt has been made to experimentally check this hypothesis.

Preceding these sections on the apical growth studies the book contains an interesting chapter (18 pages) on the quantitative description of growth, indicating the problems involved in analysing the growth of a complex, multicellular system. This chapter sets the scene for the subsequent relatively sophisticated growth analyses of the leaves and apex. The subject of phyllotaxis, and particularly the parameters used in quantitatively describing the phyllotactic systems, are very usefully discussed in an introductory chapter (30 pages), although I found it necessary to refer to the more detailed original treatments of Richards in one or two places.

This book is a very significant contribution in terms of the elegant descriptions and analyses of growth of the shoot apex and leaves, but where do we go from here? **John Ingle**

Image Science: Principles, Analysis and Evaluation of Photographic-type Imaging Processes. By J. C. Dainty and R. Shaw. Pp. xiv+402. (Academic: London and New York, January 1975.) £9.80; \$26.00.

SCIENTISTS are constantly finding new ways of exploiting the immense capacity of photographic film for the recording of scientific data. This book will assist students to join in this enterprise, although it will hardly open their eyes to the modern alternatives to film. It deals with the theory of ideal and real photoreceptors of the photographic type, quantum sensitivity, densitometry and the fundamentals of the analysis of image resolution, image noise and the information content of images. The fundamental derivations are certainly given in a way which enables wider use and could be applied to electrooptic image recording and holographic methods, but the techniques themselves are not explained and are scarcely mentioned in the body of the book.

In its sphere, however, this is a good textbook, helping the reader along by its use of well-chosen diagrams and exercises.

Andrew Holmes-Siedle

Principles and Practice in Modern Archaeology. (Teach Yourself Books.) By David M. Browne. Pp. x+262+11 photographs. (Hodder and Stoughton: London, July 1975.) £1.50.

DAVID BROWNE'S new book is a welcome addition to the growing literature on practical archaeology, all the more so since it is written with both the layman and the would-be student in mind.

After a rather heavy start, defining certain archaeological concepts, the author moves easily through the more practical aspects of the discipline dealing first with techniques of discovery, then with excavation and finally with the treatment and analysis of materials from excavation and fieldwork. He writes clearly and with the good sense born of experience.

The layout is straightforward and the reference system excellent, in that it leads the interested reader immediately to the most significant up-to-date works without losing him in a flurry of superfluous detail. A list of the major museums is appended for good measure.

This book is to be highly recommended, it cannot fail to dispel the popular misconceptions which still bedevil the subject. For those taking part in excavations it should be compulsory reading.

B. W. Cunliffe

Biocontrol of Rodents. (Ecological Bulletins No. 19) Edited by Lennart Hansson and Bo Nilsson. Pp. 306. (Swedish Natural Science Research Council: Stockholm, 1975.) 45 Skr.

THIS bulletin presents the papers from the Nord-Mus symposium on rodents and forest damage held at Lammi, Finland, in 1974. The early papers review the problems clearly and reveal the severity of the situation especially in monoculture situations.

The greater part of the symposium was concerned with the various app-

Books brief

roaches to rodent control based on the increasing reluctance to add synthetic substances to the environment and the need and wish to control rodents by manipulating the qualities of the environment and the biology of the animals. In addition to being good reviews these papers are a stimulating challenge to biologists to pursue such topics as habitat manipulation, competitive displacement, plant repellence, social mechanisms and the feasibility of genetic control of small mammals. Such work will need a multidisciplinary approach and considerable resources. It is to be hoped that the effort and forward looking nature of this symposium will be rewarded with the assistance it deserves.

Graham Twigg

Engineering in Medicine. By B. McA. Sayers, S. A. V. Swanson and B. W. Watson. Pp. vii+103. (Oxford University: London, May, 1975.) £3.25.

THIS is a curious book but I am afraid it does not quite live up to the description on the cover: "a selective review. Using this as a basis, the authors then discuss prospects and priorities—addressing the problem of identifying developments that should be supported . . ."

I have great sympathy with the authors: everyone in the bioengineering field has opinions on the future of bioengineering and of bioengineers; but if the main part of the book is intended to give an authority to the views contained at the end, apparently addressed to the health departments, it does not succeed very well. I think it is unfortunate that they made the review so wide because, even when one knows the difficulties involved and accepts this explanation, the uneven treatment is still disconcerting. Their technique of condensing infor-

mation has led them to use a profusion of expressions such as "clearly", "on the other hand", and "of course" which is also unfortunate in a book of this type.

It is simply not possible to determine for whom this book has been written. It seems to have been put together as a background book for first year students but someone has thought that it was too difficult and one chapter has more than forty phrases in parenthesis in its twenty pages which give explanations in a kindly way ranging from "features of signal shape (waveforms as they are called . . .)" to "fluid outflow (mainly as urine)". This underlies the reviewer's difficulty: if one cannot determine the real aim it is difficult to judge the value; one might hazard a guess, however, that it was not particularly great. It may be, indeed, that the purpose of the book is an expression of personal opinion on scientific management but it is hard to imagine that those able to influence the organisation of research would read right through to the last chapter, which is a pity.

D. C. Simpson

Fracture of Brittle Solids. (Cambridge Solid State Science Series.) By B. R. Lawn and T. R. Wilshaw. Pp. ix+204. (Cambridge University Press: Cambridge and London, August 1975.) Boards £7.20, \$22.00; paper £3.80.

THIS excellent little book offers a comprehensive, readable, and up-to-date survey of studies of the conditions and mechanisms in the fracture of materials. Griffith's concept of energy balance provides the basis and unifying concept of the treatment. A careful consideration of the macroscopic, molecular and atomic contributions to the energy extends the validity of the concept in a most convincing way, not entirely limited by the adjective "brittle".

The authors write from the standpoint of physical metallurgy, and the strength of the book lies in its detailed and convincing treatment of the physical processes involved in fracture. Mathematical formulations based for example, on the theory of elasticity are quoted, not derived, and the book is therefore complementary to the various monographs on fracture mechanics. Much useful information is presented in diagrammatic and tabular form, with comments in the text.

The book should remain a requirement of the serious student of strength of materials for many years.

J. W. Craggs

obituary

Sir George Thomson, who died on September 17 at the age of 83, was famous for the discovery of electron diffraction. This classical experiment confirmed the hypothesis of de Broglie, and the basis of Schrödinger's wave mechanics, and it also opened the way for an important new technique, which has become an indispensable tool of solid-state physicists and others.

He shared the 1937 Nobel Prize in Physics with Davisson who, with Germer, had seen electron diffraction independently of Thomson, at almost the same time in 1927. They were led to the discovery by an accident, which they described in their fundamental paper, whereas Thomson, inspired by the new theory, knew that such an effect was likely and set out to find it. In his Cornell lectures, which describe the early experiments, he omitted, with characteristic generosity, to mention this difference.

His work depended on a full appreciation of the then new theories and of fundamental physics, and also on the skill and caution of a great experimenter. His discovery was not published until it had been confirmed by more checks and tests than many others would have thought necessary. This discovery, and the manner in which it was made, ensure him a place among the pioneers of pure physics, but he always had an eye for the applications.

He saw immediately the possibilities of electron diffraction as a tool, and over the years contributed much to its development; for this he put to good use not only his experimental skill and flair for the technical, but also his mathematical ability, proved by gaining Firsts in Parts I and II of the Mathematical Tripos. Another subject that attracted his interest was aeronautics, with which he became involved during

the First World War, and which remained a major interest for some time afterwards. He served on the Aeronautical Research Committee at the beginning of the Second World War.

In the 1930s he became interested in neutron physics, and, with his eye for applications, took up the problem of nuclear energy as soon as fission had been discovered. A committee under his chairmanship, set up on his initiative, studied the possibilities of slow-neutron fission. When it became clear that the short term possibilities depended on fast neutrons, he became chairman of the new 'MAUD' committee, whose report led to the project being given high priority in Britain, and probably also accelerated the pace of work in the United States.

After the Second World War, another fundamental field of physics with potential applications aroused his interest. He started to study plasma physics as a means of reaching the high temperatures required for a controlled fusion reaction. This hope has not yet been realised by anyone, but Thomson and his collaborators made important contributions to the early stages of the work.

He was the son of J. J. Thomson, the discoverer of the electron, the founder of a great school of physics in the Cavendish Laboratory, and a great personality. It is often difficult to follow such a father in his own profession, but 'G.P.' did not seem conscious or embarrassed by being so overshadowed. This was no doubt due to his attitude, which was completely lacking in self-consciousness, but was governed by a warm interest in other people and a concern for the essence of the problem in hand. In his many contacts with committees and with administrative problems, there were, of course, occasions when people disagreed with

him, but they were always able to respect his point of view, and the dominant image that one took away from any encounter with him was of absolute integrity, warm humanity, and frank, even blunt, talk. His action in sharing his Nobel Prize with the technician who had been involved in the discovery is characteristic not only of his decency, but of his belief in the importance of technical innovation for the progress of the subject.

One might well apply to him a comment he made when writing about his father: "He was by no means the conventional scientist guided always by logic—if indeed such a creature exists. He was guided by intuitions, not always without prejudice."

George Paget Thomson was born in 1892, educated at the Perse School and Trinity College, Cambridge, where he obtained Firsts in the Mathematical Tripos, Parts I and II, and in Natural Science Part II. His teaching at Corpus Christi College was interrupted by the First World War, when he served in France, transferring to the Royal Flying Corps. He returned to Cambridge in 1919 and was Professor of Natural Philosophy in Aberdeen from 1922 to 1930; he moved to the chair of physics in Imperial College where he remained until he became Master of Corpus in 1952. He retired from that post in 1962, but remained active in many capacities to the end. Among his numerous honours were his knighthood in 1943, the Hughes (1939) and Royal (1949) Medals of the Royal Society, the Faraday Medal (1960) and the presidency of the Institute of Physics (1958–60) and of the British Association (1960).

After the tragically early death of his wife in 1941 he always found time, among his heavy commitments, to remain close to his four children.

announcements

International meetings

December 12–17, **Water resources: water for human needs**, New Delhi (C. V. J. Varma, Indian National Committee for International Water Resources Association, Central Board of Irrigation and Power, Kasturba Gandhi Marg, New Delhi 110001, India).

November 20, **Energy transfer in photo-synthesis**, London (Dr G. S. Beddard, Davy Faraday Research Laboratory, The Royal Institution, 21 Albemarle Street, London W1X 4BS).

December 9–11, **Second international conference on electrical safety in hazardous environments**, London (Anne-Marie Cunningham-Swendell,

The Institution of Electrical Engineers, Savoy Place, London WC2R 0BL).

December 29, **Gordon Research Conference: Metals and metal binding in biology**, Santa Barbara (Dr A. M. Cruikshank, Gordon Research Conferences, Pastore Chemical Laboratory, University of Rhode Island, Kingston, Rhode Island 02881).

October 30, 1975

Hushing up Concorde

It is indisputable that Concorde is, by today's standards, a noisy plane on take-off and landing; no public relations exercise nor appeal to patriotism can allay the displeasure (at its mildest) that Concorde causes in the region of London Airport. But we are supposed to be objective scientists, and therefore not to resort to emotional phrases and subjective opinions when there exist adequate instrumental and numerical yardsticks.

The science of noise is still in a relatively primitive state, but there is general agreement between engineers, airlines and governments that the EPNdB scale (Effective Perceived Noise Decibels) is, at least for the present, an acceptable measure. This scale makes allowance for the duration of the noise but, as it is an average, obviously does not report short term fluctuations. Present noise standards at London Airport would require Concorde, weighing about 400,000 pounds on take-off, to generate no more than 107 EPNdB. Modern subsonic planes of comparable weight such as the DC-10 and L-1011 meet these standards with at least 6 dB to spare. Concorde seems, on average, to fail to meet the standards by several decibels. Figures generally indicating this have been issued both by the Department of Trade and by the Greater London Council within the past two weeks. Values on individual occasions fluctuate substantially; sometimes the noise is as much as 10 dB above the standards, whereas on 20 to 30% of flights the standards are satisfied.

Obviously, that is worrying enough in itself, but an equally major cause for concern is that such figures could have been withheld until such a ridiculously late stage in Concorde's development. It is absurd that extensive official documentation on noise appears only when planes have been painted in their owners' colours and bookings are being made for the first commercial flights, and, moreover, when the question of noise has become central for deciding whether there shall be operations into New York. Surely scientists and engineers could have made such predictions years ago.

They did. In 1972 Mr Michael Heseltine, then Minister for Aerospace, told the House of Commons the projections for 1975 noise levels for Concorde and subsonic jets. His figure of 114 EPNdB looks in hindsight about right, and did not look too offensive when placed alongside Boeing 707-320C and 747-100 figures. But what Mr Heseltine did not do—as Andrew Wilson pointed out in his book *The Concorde Fiasco* (Penguin, London, 1973)—was put Concorde's noise properly in context with the quietened versions of these noisiest subsonics. New models and retrofitted older planes were, even in 1972, achieving 6 dB reductions on the figures quoted for their noisier brothers. Between 1972 and 1975

there has been, any neighbour to an airport will testify, quite impressive noise reductions on subsonic planes. Concorde now sticks out like a sore thumb.

What then possessed those in charge of Concorde to soldier on, in the face of these depressing figures? The answer must have been a combination of immense technological momentum and confidence that regulations at London Airport would be no obstacle (though heaven knows where the plane would land) or a belief that something technological would turn up.

The only technological fix that would have been certain to reduce noise would have been to replace the Olympus engines (which are turbojets) with by-pass engines which, under names like turbofan and fan-jets, power many planes—including the supersonic Tu-144. But Olympus engines have been associated with Concorde from the very beginning, and design had been so carefully optimised around the Olympus that the idea was unthinkable. Beyond such a change, there is a very little. Talk of inexperienced pilots and improved antinoise procedures is a red herring. And devices such as the Thrust Reverser Aft and the spade silencer have not lived up to the promise that test-bed trials held out.

Blessed with hindsight, we can now see that in the early 1970s there were no well established grounds at all for believing that Concorde could meet airport regulations. This state of affairs is now confirmed just at the time that New York is looking at the noise problems.

The story has some rather unpleasant implications for the relationship between government and science and technology. Those who worked in noise were aware, years ago, that the Concorde problem was essentially insoluble, and that the chances of finding a palliative in a strictly limited time were negligible. And yet this message never got through to, or was ignored by, those who might, given a few years, have found political or administrative solutions which would have alleviated the present situation. "We couldn't write to the papers about it", one engineer told us, "quite apart from the risk of professional suicide, we knew that an immense public relations effort would be mounted to demonstrate how limited the horizons were bound to be of one man in one laboratory."

Whistle blowing is a risky enterprise, and many whistle blowers have suspect motives. But if the present Concorde problems are the result of a studied decision to override scientific and technical advice and simply to put on a brave face, perhaps one of the few good things that could come from this whole affair would be a more adequate exposure of the terms on which governments, and industries that governments encourage, use scientific advice. □

Aage Bohr, following in father's footsteps.

Why they were worth it

Peter Hodgson assesses the achievement of the physics Nobel prizewinners Bohr, Mottelson and Rainwater; and overleaf, Michael Stoker writes about the winners of the prize for medicine, Dulbecco, Temin and Baltimore.

THE physics prize this year was awarded to Aage Bohr, Ben Mottelson and James Rainwater for their fundamental work on collective motion in nuclei. Bohr is already a famous name in physics, and Aage has now received the same distinction as his father Niels, who won the Nobel Prize in 1922 for his application of quantum theory to the hydrogen atom. This is not the first time a father and son have both received the physics prize: the Braggs received it jointly in 1915 for their work on X-ray crystallography, and the Thomsons for their work on the electron, 'J.J.' for discovering it in 1906 and 'G.P.' for showing its wave nature in 1937.

Bohr and Mottelson have worked together for many years at the Niels Bohr Institute in Copenhagen, and have maintained its reputation as one of the world's leading centres for theoretical physics, while Rainwater works at Columbia University in the USA.

The work that earned them the Nobel Prize forms one of the most recent chapters in four decades of effort to understand the atomic nucleus. The early work of Rutherford and his collaborators established that there is a tiny nucleus consisting of neutrons and protons. The problem is to understand how they are bound together, and hence to explain the observed features of nuclear reactions and nuclear structure.

We can learn something about the forces between the nucleons (a term denoting either protons or neutrons) by studying the collisions of individual nucleons with each other. The forces are certainly very complicated, and it is far too difficult to calculate the properties of the nucleus directly from them. But we do know that their net effect is to hold the nucleus together so we can represent this by an overall attractive potential parametrised by a depth and a radius. Unfortunately, calculations of nuclear properties from this model showed that some of them did not agree with experiment.

This extreme single-particle model, as it was called, was superseded in 1936 by the compound nucleus model of Niels Bohr, which took full account of the way the nucleons strongly interact. According to this model, a nuclear reaction takes place firstly by the capture of the incoming particles by the nucleus, followed by a relatively long period when its energy is shared and re-shared among all the nucleons. Finally by a statistical fluctuation enough energy is concentrated on a nucleon or group of nucleons near the nuclear surface to enable it to escape.

This model worked very well and was able to account for many nuclear

reactions, until in the 1940s it was found that many properties of the nucleons show marked changes whenever the number of neutrons (or protons) was one of the so-called 'magic' numbers 2, 8, 20, 28, 50, 82, 126, . . . This pointed to some sort of shell structure, as with atomic electrons, and these numbers were shown to follow readily from a model with a term effectively depending on the orbital angular momentum and the spin of the nucleons added to the central potential already considered. This potential has energy levels, which when filled with nucleons, one in each possible state to satisfy the Pauli exclusion principle, give automatically the magic numbers. For their independent discoveries of this Maria Mayer and Johannes Jensen were awarded the Nobel prize in 1963.

It was puzzling that the compound nucleus model requires the nucleons to interact strongly, while the shell model requires that they interact so weakly that they can follow relatively undisturbed orbits in the nucleus. This paradox is understood when we realise that the Pauli exclusion principle forbids most of the collisions that would otherwise take place within the nucleus because they would lead to states that are already occupied. A particle entering the nucleus from outside, however, has much higher energy so that the final states are seldom occupied and the interaction takes place strongly. This absorption was included in the simple models by allowing the potential to become complex at higher energies.

In all this work it was assumed that the nucleus is spherical, but data began to accumulate showing that some nuclei are quite markedly deformed. This evidence came mainly from their large quadrupole moments. Closed shell nuclei, in which the neutron and proton numbers are both magic, such as ^{16}O , ^{40}Ca and ^{208}Pb , are spherical, as is to be expected from the high symmetry of the closed shells. For other nuclei, the deformation increases with the number of nucleons outside the closed shells. It is notable that the quadrupole moment is always positive immediately before a shell is filled and negative immediately after. The quadrupole moments calculated from the orbitals only of the nucleons outside the closed shells were inadequate to explain to date.

In 1950 Rainwater suggested that the extra nucleons can polarise the core so that it becomes spheroidal. Thus the shape of the nucleus results from its own stabilising forces, tending to make it spherical, and the forces from the extra-core nucleons, which tend to deform it.

If the nucleus is considered to be a liquid drop, the surface and Coulomb energies are proportional to the square of the eccentricity, for a spheroidal deformation. The effect of the distortion on the individual shell model orbits can be found by calculating the eigenvalues for a particle in a spheroidal potential, and together they give an energy that decreases linearly with the eccentricity e . Thus the total change in energy due to the distortion is

$$\Delta E \approx c_1 e^2 - c_2 e$$

and the stable shape for minimum energy is given by $e = c_2/c_1$. The constants c_1 and c_2 are known quite well, and Rainwater showed that this gives quadrupole moments that are similar to those found experimentally, and accounts for their variation with shell structure.

This vital suggestion removed the main difficulties about nuclear quadrupole moments, and provided the essential basis for a detailed theory of nuclear deformations. This was developed by Bohr and Mottelson and collaborators during the following decade. In their earlier calculations they treated the nuclear core as a charged, deformed drop of nuclear liquid interacting with the few nucleons outside the core. The motion of the core is described by a few dynamical variables, while the extra-core nucleons are treated individually. In later work they considered all the nucleons, and allowed them to move in a non-spherical potential, which represents the long range correlations between the nucleons.

Bohr and Mottelson recognised that nuclear deformations can be of two types, static and dynamic, or more simply that nuclei are either hard or soft. Hard nuclei keep their shape, but if they are deformed they can be set into rotation, like a rotating rugby football. The energy levels of such a system can be calculated quantum mechanically, and are given by the formula

$$E = \hbar^2 J(J+1)/2I$$

where I is the moment of inertia. In many nuclei, particularly the rare earths, whole series of rotational bands, each with many states, have now been identified. The theory, with its more detailed development, predicts these levels very accurately.

Soft nuclei, on the other hand, are easily given oscillations or vibrations, like the wobbling of a jelly. Calculated energy levels agree with those observed in some nuclei. The vibrational spectra are not as well marked as are the rotational spectra in hard nuclei because the vibrations are easily coupled to other types of motion, thus complicating the spectra.

One of the best known examples of nuclear collective motion is fission,

Rainwater (left) and Mottelson: prize for work on collective motion in nuclei.

when the nucleus breaks into two nearly equal parts. Niels Bohr did much of the early work on fission during the war years using the liquid drop model of the nucleus. In the 1950s Aage Bohr approached the problem from the microscopic point of view, in terms of the energy states of the fissioning nucleus. He showed that low energy fission takes place through very few reaction channels even though the level density is very high. This happens because most of the energy of the incoming neutron is spent on deforming the nucleus instead of exciting it internally. He has also made important contributions to the theory of the mass distribution of the fission fragments and of their angular distribution.

These rotational and vibrational models of the nucleus are known as collective models because unlike the independent particle or shell model for spherical nuclei they both require the nucleons to show collective or bulk motion. The nucleons are still moving rapidly along the independent shell model orbits but on a longer time scale the orbits change so that there is a resultant bulk motion of the nucleons, first in one direction and then in another, that forms the rotation or

vibration of the nucleus as a whole.

The great achievement of Bohr and Mottelson was to put all this work on nuclear collective motion on a sound and detailed quantum mechanical basis, and to apply the theories to account in detail for the properties of deformed nuclei throughout the Periodic Table. The hard nuclei are represented by a potential whose surface is expressed as a series of spherical harmonics, each with a coefficient giving a measure of the quadrupole, octupole, hexadecupole . . . deformations. The vibrations are similarly represented by dynamical deformation parameters that vary with time. All this work is described in detail in a monumental work on nuclear structure that Bohr and Mottelson have been writing for many years and which is being published in three volumes, the first of which appeared in 1969. These grew out of a series of lectures that is a continuing feature of the life of their institute. They are still full of activity, and will continue to contribute to our knowledge of nuclei, and to provide a source of stimulus and encouragement to younger workers in the years to come. □

Peter Hodgson

Nobel Prizes: 2

ALTHOUGH the pioneer discoveries on tumour viruses by Peyton Rous were begun in 1911, it is only in the past two decades that the particular importance of these viruses has been recognised, not only as causes of cancer, but as vital keys to the structure and function of animal cells. We now know that a prime feature of these tumour viruses is their ability to exist as integral parts of the chromosomes of their hosts, carried indefinitely from generation to generation in tumour cells, sometimes in normal cells, and even in germ cells, from parent to offspring. It is not surprising that the 1975 Nobel Prize for Medicine should be awarded to David Baltimore, Renato Dulbecco and Howard Temin, the three scientists whose discoveries revealed a phenomenon with such wide implications.

There can be few research workers with such a sustained harvest of discoveries as Renato Dulbecco. After graduating in medicine in Italy, and a period of initiation into phage genetics with Salvador Luria, he moved to CalTech in 1952, and during the next few years, with Marguerite Vogt, his long standing collaborator, he set the scene for the whole new era of quantitative animal virology in cultured cells which has followed. This was begun by the development of the plaque assay, a precise and direct measurement of virus particles, making possible for the first time a detailed analysis of virus growth and virus antibody interaction, to say nothing of the isolation of genetically pure stocks of virus, an essential first step for the subsequent isolation of mutants. Much of this early work was with polio virus and provided the basis for the development of the live poliomyelitis vaccines.

In the late 1950s, however, interest in Dulbecco's laboratory was shifting to the tumour viruses, and it was here that Harry Rubin and Howard Temin (then a graduate student) first successfully applied Dulbecco's quantitative approach to the study of Rous sarcoma virus, by developing an assay of transformation, a cancer-like change induced by the virus in cultured cells. Meanwhile, Dulbecco and Vogt had concentrated on the recently discovered polyoma virus from mice, and in 1959 they reported transformation by this virus leading not only to abnormal growth of cells in culture, but also to the development of tumours when the cells were transplanted into animals. In the next few years, which included a sabbatical period in Glasgow, Dulbecco and his associates then went on

to characterise the DNA which constituted the genome of the virus. It was found to be a small circular molecule, and this alone was sufficient to produce the neoplastic transformation.

The studies of transformation and tumour induction by polyoma virus, and the closely related SV40 virus of monkeys, soon posed a crucial question concerning the fate of the virus, and its role, once the initial neoplastic event had taken place in an individual cell. Did the virus simply hit and run, or did it continue to multiply and persist in all the progeny cells? If the latter, was it essential for the continued abnormal behaviour of these cells? It was soon shown by Dulbecco and Vogt that the presence and growth of virus particles were not essential features of the transformed state, but there were indications, from the work of Habel and others on new cell surface antigens for example, that viral coded information might be present in the cells. The ring structure of the viral DNA had, in fact, suggested to Dulbecco that it might be incorporated into the chromosomal DNA of the host in a manner similar to prophage in lysogenic bacteria.

It was in 1967 and 1968, after moving to the new Salk Institute as a Founder Fellow, that Dulbecco and his associates produced the first evidence that this was, indeed, the case. First with Watkins the presence of a complete set of viral genes was demonstrated in apparently virus-free transformed cells, by fusion with a second 'permissive' cell which released the block in virus growth. Then with Westphal, and later with Sambrook and Srinivasan, molecular hybridisation was used to show that viral nucleic acid sequences were not only present in the transformed cells, but were chemically attached to the chromosomal DNA of the host. This fundamental series of discoveries, and others that followed, showed how, after the initial transformation or tumour induction, the virus might persist and so affect the behaviour of all the descendants of the original cell.

To investigate the role of the tumour virus genes in the cells, Dulbecco had begun the study of conditional mutants of the viruses, first of all at CalTech with his student, Fried, who isolated the *tsa* mutant of polyoma virus, and subsequently with Vogt and Eckhart at the Salk Institute, on a whole series of new mutants. Finally, as if this were not enough, Dulbecco has produced major contributions on the physiology of the transformed cells and their normal counterparts, work which has actively continued since he moved to London in 1972.

The discovery that a DNA-containing virus could persist by integration of its genome in an animal cell was

remarkable enough, but there was at least a model available in the integrated prophage of lysogenic bacteria. The RNA-containing tumour viruses were a different kettle of fish altogether—or so it seemed. Rous sarcoma cells, or cells transformed in culture by this and similar viruses, may admittedly harbour virus particles, but since the viruses contain RNA alone there seemed to be no way in which the genetic information could be transferred into DNA to allow a stable relationship with the chromosomes of the host cells. Nevertheless, the virus-cell relationship was clearly very stable, and there were preliminary indications that some of the RNA tumour viruses could be transmitted in chromosomes from parent to offspring in Mendelian fashion. It was this problem which attracted Howard Temin.

Temin had continued his early work with Rous sarcoma virus, and using virus mutants made the interesting finding that the virus could determine cell morphology. After he left Dulbecco's laboratory he moved to the McArdle Institute at Madison, Wisconsin, and there began to study the nature of the provirus, as he called it, in transformed cells. After showing that DNA synthesis was a necessary requirement for transformation, he went on to search for viral DNA in the transformed cells. Soon came his scandalous proposal that the genetic information in tumour virus RNA was first transcribed into DNA, which was, in turn, incorporated in the transformed cells. This was not, as some have suggested, an offence to Crick's central dogma, but it was, none the less, pretty unorthodox. Indeed, when Temin's first nucleic acid hybridisation data, purporting to show Rous virus DNA sequences in transformed cells, were published in 1964, they were not very convincing and there was a good deal of sad head shaking. In time, Baluda produced more convincing evidence for viral DNA sequences in transformed cells which seemed to support Temin's views, but the principal stumbling block was the absence of any known enzyme system which could make a DNA copy from an RNA molecule, and it was this problem which Temin began to investigate.

Meanwhile, in 1968 David Baltimore had come to work in Dulbecco's laboratory. While there, and later at MIT, he made a series of important discoveries on the replicating form of the RNA of poliovirus, and on the processing of the newly synthesised virus proteins. He had not worked with tumour viruses, but was presumably influenced by the work going on around him in Dulbecco's laboratory, and by Baluda's recent hybridisation data. After he left to take up his position in

Boston, he began, like Temin, to look for an enzyme in Rous sarcoma virus which would synthesise DNA on a RNA template.

And so it turned out that, simultaneously but quite independently in May 1970, Baltimore, and Temin with his colleague, Mizutani, reported the phenomenon which soon became known as reverse transcription. In elegantly simple experiments they both showed that radioactive precursors were incorporated into DNA in Rous sarcoma virus particles containing RNA alone, and this DNA turned out to be complementary to the virus RNA. Baltimore and his colleagues have since gone on to investigate in considerable detail the activity of reverse transcriptase, the enzyme concerned, and in a series of outstanding papers have described most of the steps by which double-stranded DNA is constructed from virus RNA.

Many of the implications of the discovery of reverse transcription were

immediately obvious and were breathtaking in their scope. It immediately vindicated Temin's hypothesis that RNA tumour viruses persist in tumour cells in the form of DNA copies, and it was not long before Hill and Hillova demonstrated infectious DNA in Rous virus-transformed cells. This linked the work of Baltimore and Temin to that of Dulbecco, and permitted a unified view of tumour viruses in general, since they are clearly all DNA viruses at heart, at least in their stage of association with the host cells. In addition, the discovery of reverse transcriptase has itself provided an extraordinarily powerful new tool, since it makes possible the construction of highly labelled complementary DNA molecules which can be used as probes to search for similar sequences in either DNA or RNA. This has led, not to new and sensitive methods in the search for human tumour viruses, particularly those developed by Spiegelman, Gallo, and others, but

also to more general studies on messenger RNA and its relationship to the chromosomal DNA, for example, in studies on the haemoglobin and γ globulin genes. Finally, the demonstration that the flow of genetic information from DNA to RNA can be reversed has provoked a whole range of new and exciting speculations (and even experiments) on the relationships of viruses and their hosts, not least with Temin's own provoking ideas about the 'normal' role of proviruses in gene amplification and differentiation.

The discoveries by this year's prize-winners have opened entirely new prospects in virology and cancer studies, and have added a quite new dimension to molecular biology. Had he survived, Peyton Rous, who started it all and who waited 55 years for his Nobel Prize, would have been the first to express his delight at the Committee's choice.

M. G. P. Stoker

international news

THE two Venus probes, Venera 9 and 10, which soft-landed successfully on October 22 and 25, respectively, at sites some 2,200 km apart, have resulted in considerable rethinking of many ideas about the planet. The members of the Soviet Venus project, faced with pictures of sharp, angular, granitelike rocks (see picture above) instead of the expected sand, have been quick to comment. The sharp, "young appearance of the rocks" said mineralogist Aleksandr Vasilevskii, indicates recent seismic or volcanic activity, typical of a "live" planet. The sharp shadows, indicative of sunlight filtering through the cloud cover to the surface and the flat landscape, rather than the expected "gold-fish bowl effect" produced by postulated atmospheric distortion, have considerably opened up the possibilities of further visual observation of the surface, since it is now clear that the

Venus, courtesy of Moscow

from Vera Rich

photographs obtained can be considered and interpreted as received, without the need for empirical correction and compensation. M. Ya. Marov, of the Long-Range Space Communications Centre, spoke of the photographs as inaugurating a new era in space research, in which "clearly directed complex investigations" would replace the somewhat hit-and-miss efforts of the previous "age of reconnaissance". In the same mood of euphoria, *Pravda* also speculated on the possibility of manned Venus missions in the next century.

Meanwhile, the remaining data

gathered and transmitted by the probes, including analysis of the cloud cover and the optical characteristics of the atmosphere, has gained relatively little attention, and must await routine processing.

● The Soviet Minister of Education, Mr V. P. Elyutin, visited Britain and, more particularly, the Open University last week. This visit, clearly an exercise in *detente*, yielded little definite outcome, although some fields of cooperation between the Open University and its Soviet opposite number are envisaged. Mr Elyutin spoke of the possible mutual publication of materials, and mutual production of television programmes, and also joint research work on common problems such as environmental protection and also special research into the theoretical problems of higher education.

Speaking of Soviet higher education,

WHEN a federal court ruled last year that grant proposals submitted to the National Institutes of Health (NIH) should be made public on demand, a number of scientists, alarmed at the possibility that their research ideas could be plagiarised, went scurrying to Congress seeking a bill to override the court's decision. They have not had a very sympathetic hearing on Capitol Hill, however. It now seems that the best they can hope for is that their concern will be investigated by an independent commission.

Several scientific and academic groups, led by the Association of American Medical Colleges (AAMC) have been lobbying hard for a provision, designed to preserve the confidentiality of grant applications for at least a year after they have been funded to be attached to a bill extending the programmes of the National Heart and Lung Institute. But last week, the House of Representatives passed the bill with only a mild provision directing the President's Biomedical Research Council—an influential commission which is now examining NIH policies—to look into the matter and report by next May. A Senate subcommittee, chaired by Senator Edward Kennedy, will approve its own version of the heart and lung research bill in the next week or so,

but it is not expected to deal with the confidentiality issue at all.

It therefore seems likely that all the details contained in grant proposals will continue to be made available to anybody who goes to the NIH and asks to see them. Though NIH lawyers have

Science no secret, yet

by Colin Norman, Washington

interpreted the court's decision narrowly by insisting that it applies only to proposals which have been funded or which are up for renewal, many scientists are concerned that it could open the door to some trouble.

First, there is the problem of possible plagiarism. Grant applications are supposed to describe exactly how the proposed experiments will be carried out. The court ruling would make such details publicly available as soon as the grant is awarded, rather than when the final results are reported, and scientists are therefore concerned that their competitors could obtain complete details of what they are doing, carry out the experiments themselves, and rush into print before the hapless originator of the idea had been able to do so.

The court dismissed such notions, however, by pointing out that it makes

no difference whether or not "biomedical scientists are really a mean-spirited lot who pursue self-interest as ruthlessly as the Barbary pirates did in their own chosen field", because the law—in this case the Freedom of Information Act—clearly applies.

The AAMC is also worried that the court ruling could upset the peer-review process by which grant proposals are evaluated. The association contends that grant applicants will be reluctant to describe their proposed experiments in detail, and funding decisions will therefore be made by peer reviewers on the basis of sketchy information.

But Congress has been reluctant to step in and exempt grant applications from public disclosure for a number of reasons. For one thing, the Freedom of Information Act is an admirable piece of legislation which has ensured that much public information is actually made public, and legislators are therefore anxious not to weaken it. And for another, there has recently been considerable discussion in the United States of the ethics of various experiments on human subjects, and Congress is determined to ensure that details of such experiments are made publicly available so that ethically questionable studies cannot be hidden behind a cloak of secrecy.

he reported that there is no decrease in the number of scientists being trained in the USSR, since the proportion of each discipline in each year's turnout of students is held constant and at present the total student population is increasing.

● The Jubilee Celebrations of the Soviet Academy of Sciences, which, after a postponement of more than a year, finally took place in the first half of October, following a fairly predictable pattern.

Of far more significance was the press conference given by Dr James C. Fletcher of NASA, while in Moscow for the celebrations. As part of the Soviet-US cooperation in Space research, Dr Fletcher revealed, talks were going on to explore the possibility of exchanging ground equipment enabling each partner to monitor the weather and research satellites of the other. In addition, in exchange for data from the American Landsat satellites, which monitor natural resources, the Soviets would provide the USA with similar data from high altitude reconnaissance aircraft, which use similar techniques of spectral analysis to gather geographical data. One interesting sidelight on the proposal is that such an exchange would throw a clearer light on to the Kosmos satellite programme. Since its inception in 1962,

this has been a useful cover-all for miscellaneous objects in space which could not be otherwise explained; not only the inevitable military reconnaissance satellites, but also failed interplanetary probes, unpublished trial runs of new spacecraft and so on. Although many objects have been identified over the years by outside observers, the Soviet space planners have never commented on the identifications, although data gathered by certain named Kosmos satellites are, from time to time, published in the technical literature. If this exchange of equipment goes forward, some new designation of satellites might become necessary. Weather forecasting is already the responsibility of the 'Meteor' series. Perhaps, rather than making certain Kosmos satellites available to the Americans, a new series of geophysical satellites might be inaugurated under another name.

The postponement of the Academy celebrations from May 1974 to October 1975 was itself something of a mystery. The official explanation was that the celebrations would coincide with the Soviet elections; furthermore, that more time was necessary for the preparations at all levels of Soviet scientific society. This second reason was echoed in the press conference given on September 25 by the new President of the

Academy, Vladimir A. Kotelnikov, who spoke of "all jubilee measures" being now complete. Nevertheless, at the time of the postponement, these excuses were felt to be incomplete. Possibly the illness of the then President of the Academy, Mstislav V. Keldysh, who resigned last May, played its part. A number of observers, however, felt that the postponement might not be unconnected with the whole problem of intellectual and academic freedom in the Soviet Union, and the possible embarrassments which might be caused should visitors from abroad refer to such questions. Whatever the truth of the matter, the three dissident members of the Academy, Andrei D. Sakharov, Igor R. Shafarevich, and Veniamin G. Levich, did receive invitations for the jubilee celebrations, thus forestalling any possible criticisms on their account.

This atmosphere of goodwill was, however, short-lived. Following the announcement that Sakharov was to receive the Nobel Peace Prize, the Tass agency began a campaign of attack directed against both Sakharov and the Peace Prize adjudicators. On October 13, Levich, who had been promised an exit visa for Israel by the end of 1975, was informed that such a visa would not, in fact, be forthcoming. □

A REGULAR visitor would have been surprised: all the parking places were taken. Latecomers had squeezed their cars into corners, rolled them on to the raked gravel paths and finally let them spill down the drive. Coming to the Royal Swedish Academy of Science for the first of last week's Nobel Prize announcements was rather exciting. The second and third times were less so. It only took one visit to realise that the parking jam was not caused by eager newsmen, but by sedate Academicians meeting in traditional session; that the low murmur heard in the imposing lobby was not because the crowd was tense and suppressed, but because it was very small; and that the single flex snaking up the stairs, pregnant with promises of a media extravaganza, led in fact to the only microphone present.

Could it, realistically, have been otherwise? Like all businesses, the media invests large amounts of resources only with the prospect of a payoff. And today's Nobel Prizes for Science do not make newspapers sell. Gone are the days when the names of even scientific laureates were likely to be household words. Gone even are the days when scientists active in the same subject were certain to know of the winners. What physicist working before the mid-1950s had never heard of Fermi, Blackett or Cockcroft? Today's laureates are unlikely to be known outside their own specialisations.

This is not to question the distinction or value of the contributions made by the present prizewinners. It is merely to recognise the greatly increased scope of scientific endeavour, the pervasiveness of specialisation and the replacement of the individual scientist working in his laboratory by the team. Small wonder that the old doyens, known by all in the subject, no longer exist.

It should not really have been surprising to find so few newsmen there. The trends which have influenced the development of science have, after all, also left their mark on the reporting of it. The scope and teamwork of newsgathering has been dramatically broadened by the wire services. What role can be played by the individual pressman—be he ever so enthusiastically crouched over his telephone—in the face of the news giants whose technology will have bounced the headlines across the globe almost before he has had time to dial his number? Those few reporters who went to the Academy's announcements swapped stories about how it used to be when news sleuths concocted elaborate schemes to get the laureates' names out first: when they held lines open in local telephone boxes and waited for

the names to be communicated by pre-arranged signals from collaborators inside the Academy building—and what happened once when a man sufficiently like the key informant to be mistaken for him came out and innocently lit a cigarette, thereby putting into action an intricately planned (and later highly embarrassing) series of events.

A prize system which rewards individuals when teamwork dominates scientific research, and which rewards so few individuals when so many are now in the field, is bound to cause some

Letter from Sweden

from Wendy Barnaby, Stockholm

disenchantment. In spite, and partly because, of this, the distinction of being a science laureate is as high as ever. If the reporters' indifference is easy to understand, so also is the winners' delight.

● Sweden's ambitious nuclear energy programme is amply underpinned by the country's uranium resources, which are estimated to be the West's largest in the price range (1968 figures) of \$10–15 a pound (cheaper uranium can be mined for less than \$10 a pound). Knowing it is there is not the same as getting it out, however. The State Power Board, the government-owned nuclear energy research company AB Atomenergi and the mining firm LKAB are keen to start extracting uranium from 15 km² around South Billingen, about 350 km south-west of Stockholm. But they are not the only ones with their eyes on the area. To begin with, the region is populated and the soil is good for agriculture and forestry. Cultural historians prize it for its dozens of ancient monuments (including five gravesites dating from the Iron Age). In view of this, the military's interest seems particularly callous: they want to use it for a shooting range. And there has also been talk of the suitability of the land for limestone mining.

● Sweden and Yugoslavia are expanding their scientific cooperation. Under an agreement signed recently in Stockholm, scientists and experts from the two countries will exchange visits of 10 person-months a year, symposia will be held and the traffic of scientific and technical journals enlivened. A spokesman for the Royal Academy of Engineering Sciences, which negotiated the agreement, said that the specific areas of cooperation had not yet been decided but that they would be in applied rather than basic science.

The agreement is similar to those Sweden has with other East European countries in that, although each sig-

natory can nominate scientists it would like to host, the final decision rests with the other's authorities. In this sense it is a less exciting arrangement than that concluded this year between the Swedes and the Russians, in which each undertook to send the specific experts requested by the other. In practice, of course, this aspect of the undertaking may make very little difference to the work actually done. For the moment, it is enough that each side wants the volume of this work to increase.

● Asbestos, and its use in working environments, is the subject of new regulations issued by the Swedish Work Protection Board. In the face of increased consciousness of the dangers of exposure to asbestos dust, the victims of which at present number about 200 (including some cases of lung cancer), the new regulations aim to minimise its use, to regulate unavoidable use and to educate the users to the dangers involved.

Sweden uses about 30,000 tons of asbestos annually, half of it raw and half in the form of ready-made products such as asbestos cement. Although its use is being discontinued where substitutes can be found—as in the manufacture of torpedo boats—it seems difficult to replace it totally with safe materials. Brake linings, for example, still depend on asbestos to withstand great heat. Given this situation, total protection of the working population from this particular environmental hazard still looks to be some way off.

● Taking measures to improve working conditions is not Sweden's only activity in this area. "The working environment" is one of the obligatory subjects for students beginning university-level education in trade techniques. This autumn, eight trial courses in the techniques of the clothing, food, paper, forestry, workshop and steel industries are being held around Sweden for people who have had basic training and at least four years of employment in one of these fields. The idea is to educate experienced workmen for more responsible positions—vocational trainers, production and control technicians, foremen—within the various industries.

At Eskilstuna, to the west of Stockholm, 30 employees from different workshops—among them, sheet-metal workers and tool-makers—are starting a course that will demand 40 hours a week for three terms. Besides "the working environment", they are taking off with six subjects: Swedish, physics, mathematics, materials, drawing and organisation. There seems to be no uncertainty about their employment prospects after the course. □

THE Arab League Educational, Cultural and Scientific Organisation (ALECSO) and the United Nations Environment Programme (UNEP) have started a Regreening of Arab Deserts Programme. Task forces of consultants have visited Arab countries to interview leaders of scientific projects, heads of government departments concerned with land reclamation plans, and institutes of research concerned with desert studies and with aspects of land use in arid territories.

Their aims are to identify national experiments for applying science and technology to the fight against desert creep and to the reclamation of desert lands, the conservation of surface deposits, the use of saline water for irrigation, the improvement of technologies for 'subsurfacing' with special materials including asphalt and asphalt-like substances, the conservation of natural pasture and experimental range management, animal breeding for improved stock, sand dune stabilisation, farming in desert oases (underground water resources) and to the integrated development of natural resources and nomads.

A coordinated intergovernmental research programme, in which the Arab countries will participate, will use the information and data provided by the task forces as a basis for consultations on the scientific content, plan of action and budget of the programme. The aim is the rational use of scientific knowledge and technical innovations in halting desert creep which is now proceeding at an alarming rate, and regreening extensive tracts of man-made deserts. Also planned are a study of human impact on nature and natural resources in Arab countries and a survey of the existing national institutional arrangements dealing with deserts.

Task forces have already prepared interim reports on their visits. In Libya they found that trees planted in open sand have little chance of survival because the movement of the sand by the wind in summer, when the soil is dry, either buries them, uncovers the roots or sandblasts them. So temporary stabilisation is carried out by spraying with a petroleum mulch heated to a temperature of 40–60 °C. The cost of spraying 1 hectare is about 120 Libyan pounds (\$375).

In Saudi Arabia, a number of nurseries have been established on a total area of about 18 acres, producing 600,000 saplings a year (comprising the native *Tamarix gallica* and *T. aphylla*, and such introduced species as *Eucalyptus camaldulensis*). The result was that sand dune encroachment from the north and north-east was checked and 14 villages menaced by sand dunes have been protected. Afforestation amounts

to 1,250 acres (10 million trees) and other projects include the drainage of swamps and water-logged ground, and the establishment of a national park.

A land reclamation project has been started at Taourgha, 200 km east of Tripoli and about 25 km south of the Libyan coast. Irrigation is by artesian water from the Taourgha spring, which flows freely at the rate of 3.0–3.25 m³ s⁻¹ or about 250,000 m³ d⁻¹ and contains about 2,500–3,000 p.p.m. of soluble salts (that is, class 4 water, with very high salinity). The total area involved in the project is 3,000 hectares,

The Arab World

from Salah Galal, Cairo

and the growth of crops (alfalfa and barley) has been quite satisfactory with water containing 3,000 p.p.m. of dissolved salts. The soil is quite permeable, the drainage is adequate, and irrigation water is applied in excess to provide considerable leaching (50% leaching requirement).

In Tunisia the government established in 1962, with assistance from the UN Development Programme and UNESCO, a Research Centre for the Utilisation of Saline Water Irrigation (CRUESI) to study the prospects of irrigation with saline water and to train specialists and technicians. CRUESI has six field stations representing a range of soil conditions, water quality and climate, and has in hand a series of well designed experiments combining various water quantities, soil treatments, land preparation and crops. Tested crops included alfalfa, clover, maize, beans, pimientos, rye grass, watermelons, sugarbeet, artichokes, fodder sorghum, tomatoes and cotton. The experiments carried out since 1962 have already produced valuable scientific information.

The ALECSO/UNEP task force of consultants has recommended a co-ordinated research programme to restore and manage rangelands in Arab countries, with studies on the recovery and succession of vegetation types and changes in biomass and production with regard to grazing; selection of useful native species from the point of view of their occurrence, phenomenological development and ecological relationship; the improvement of practices like range pitting and contour furrowing; studies to control desert creeping and sand dune shifting (by such methods as mulching, wind breakers and the placing of brush barriers); wind strip cropping control; and the limitation of soil erosion by wind and water.

● Professor Mahmoud Mohamed, professor of radiotherapy and nuclear

medicine at Cairo University and ex-Minister of Public Health in Egypt, has put forward a strategy for cancer control in developing countries, with Egypt as a model. It stresses the inadequacy of basic and central health information and documentation centres (which means that assessing health problems is usually a matter of empirical estimation), the inadequacy of resources and investments for upgrading existing services and research so that the attention of the health administration is usually focused on curative rather than on preventive services; and the lag which usually occurs between health development schemes and manpower development. Suprastructure development in cancer research is usually not planned or linked to existing health priorities, says Professor Mohamed, and furthermore, it suffers from factors as diverse as a brain drain, low socio-economic standards, and illiteracy—a pertinent feature of underdevelopment which impedes the extension of health education. Short life expectancy and high infant mortality rates add to the problems of cancer control in Egypt, with the real incidence and mortality rate still unknown and information available only in the form of relative frequency data. The estimated number of new cases each year is about 10,000–12,000 (Cairo University Hospital 200; Cancer Institute 2,000; Alexandria University Hospitals 1,500; Ain Shams University Hospitals 300; Mansoura University Hospitals 200; Tanta University Hospital 530; Assiut University Hospitals 120; Ministry of Public Health Hospitals 500; private cases 3,800.)

The most common cancer, in the male, is that of the urinary bladder (21–24%) and the most common in the female is cancer of the breast (20% of all female cancer cases attending the radiotherapy department of the Cairo University Hospitals). Most patients present themselves in the late stages of their disease to the 10 treating centres (all of which are teaching centres) or to 40 general hospitals and 159 district hospitals with inadequate or old equipment.

The proposed strategy includes decentralisation of the diagnosis of cancer; centralisation of treatment, manpower development and research in university centres; relying on the GP and his team for early detection; concentrating research resources on epidemiological aspects as a priority; establishing the registration of cases as an integral part of a general health registry; and the establishment of cancer control teams in teaching hospitals.

● UNESCO plans to convene a Conference of Ministers in Arab States Responsible for the Application of

Competition 2. Limericks to illustrate scientific principles. An enormous crop; we haven't verified that the selection that we print are original, and in at least one case the science is wrong (no prizes for pointing out errors). £10 to G. J. S. Ross of Harpenden, Hertfordshire; a clear winner with black holes, and also runner up with plate tectonics.

A pedantic astronomer said—gravity
Is causing semantic depravity.

These stars may be black
As light outflow they lack,
But holes? there's no room for a cavity.

G. EDWARDS

There once were two frogs of Gondwana
Who vowed ne'er to part till Nirvana,
But each met its fate

On a separate plate:
He lies in Brazil, she in Ghana.

G. J. S. ROSS

"Apollo to Mission Control—
We are almost in reach of our goal,
But our readings of G
Seem excessive to me,
So we may be inside a black ho . . .

G. J. S. ROSS

Poor John could not savor a rose
Despite hard proboscis blows
"My genes", explained he,
"Have an A for a G
So I suffer a code in the nose."

A. MEHLER

A plumber by name of Fred Slaughter,
With a wife and extravagant daughter,
Shouted, "Praise and acclaim
For whatever's to blame
For the anomalous expansion of water."

Competition No 3

Archimedes is said to have discovered his most cherished principle in the course of messing up the bathroom floor, Newton upon being disturbed by a passing apple. Fleming left the window open and came home to penicillin. Readers are asked to provide a fictitious account (short) of similar momentous discoveries which were happened upon by chance. If stuck for topics, they might try their teeth on pulsars, double helices or good old continental drift. Closes (Dec. 5). □

Science and Technology to Development (CASTARAB) in 1976, to be organised with the cooperation of ALECSO and the Economic Commission for West Asia (ECWA).

As a first step in preparation for the conference, a preparatory meeting of experts was held in Kuwait to advise the Director General of UNESCO on the preparation of the agenda and the documents for the CASTARAB conference.

It finally recommended three main themes for the conference: trends in the national science and technology policies of Arab states; regional co-operative research projects relating to natural resources, energy, food resources and environmental quality; and integration mechanisms for science and technology in the Arab states.

● Saudi Arabia has invited Egypt to make use of the Centre for Applied Geology (CAG) which had been established in Jeddah, close to the Arabian shield (which is rich in ores and minerals). The CAG is at present offering courses in mineral exploration, hydrogeology and engineering geology. It offers the degree of Master of Science and has a two-year geology technician training programme leading to a technical diploma.

The centre also offers an opportunity for geologists from Saudi Arabia and neighbouring countries to be trained, and students obtaining their master's degree with outstanding grades may be granted a government scholarship for completing their studies for a PhD abroad.

● A study on the brain drain of physicians in Egypt shows that the main concentration in the Egyptian population is in the Nile Valley and its Delta, where the limited amount of land space means that about 99% of the total manpower is crowded into about 3.5% of the total surface area of the country. Consequently there is a regular redistribution of manpower and Egyptian physicians tend to migrate (both internationally and intranationally) with the UK and the USA proving the most attractive destinations.

Apparently, African countries prefer Egyptian physicians, with the result that there is a migration of medical students from Arab and African countries to the Faculty of Medicine at Cairo University. This year the main exporting countries for medical students were Saudi Arabia (297), Libya (181), Palestine (134), Jordan (121), Sudan (114), Kuwait (102), Lebanon (88) and other Arab countries (278)—a total of 1,315 from Arab countries; they also came from South Africa (59), Malaysia (48), Nigeria (26), other African countries (41), from Pakistan (25), and other countries (54) (making a grand total of 1,568 foreign students).

Statistics show that physicians left jobs in the rural areas at the following rates: 1972 (5%), 1973 (4.2%), 1974 (5.8%); and the number of Egyptian physicians working abroad were spread in the following way: in Arab and African countries in 1965, 269 (76.3%); in African countries 23 (6.4%); and in other countries 61 (17.3%). □

Carcinogenic agent?

A SOLVENT used extensively in academic and industrial laboratories may be a potent carcinogen when its vapours are inhaled, according to tests carried out by scientists at the DuPont corporation in Wilmington, Delaware.

Known as hexamethylphosphoramide (HMPA), the solvent has long been recognised as acutely toxic and as a skin irritant, but there had been no previous indication that it is carcinogenic. The DuPont study found, however, that rats developed a rare nasal cancer when they inhaled small amounts of HMPA for 6 to 8 months. Although the study has not yet been completed, Dr J. A. Zapp, Jr, Director of DuPont's Haskell Laboratory for Toxicology and Industrial Medicine, wrote a letter to *Nature* to "urge everyone using HMPA to handle it with the precautions appropriate to a potential carcinogen".

The experiment, which was started in December last year, involved exposing rats to amounts of HMPA ranging from 0 to 4,000 parts per 10⁶ for 6 hours a day, 6 days a week—in other words for periods of time corresponding to occupational exposure. After 8 months, some of the rats developed enlarged noses and had difficulty in breathing, and it turned out that they were suffering from a form of nasal carcinoma. "There appears to be no doubt", Zapp said, "that this rare form of cancer has been produced . . . by inhalation exposure to HMPA at a concentration as low as 400 p.p.b.". □

correspondence

EEC directives

SIR,—In his article "A community of interests" (October 16), Lord Ashby describes as "phoney" the EEC argument that to permit lower effluent standards to a Scottish wood pulp mill than to one situated on the Rhine constitutes unfair competition.

The EEC argument is valid since the clear intention of the 1973 Declaration is to remove the question of pollution control from the realm in which market forces can operate. The situation is analogous to that of safety regulations inside the suggested wood pulp mills. Such regulations are recognised as imposing a prior cost on the production process. Society, through the legislative process, has opted for such. Price competition can begin after these legislated costs have been paid—and a company can only stay in business if its rivals are obliged to do the same.

B. A. MARDALL

London, UK

SIR,—Regarding Lord Ashby's article on EEC directives and pollution, there is surely now real evidence that sewage in seawater around beaches is dangerous to health. I refer to work by Dr H. Williams Smith, a bacteriologist, who analysed samples of seawater from fifteen beaches in England and Wales, and found high concentrations of *E. coli* which had clearly got there from sewage. As Dr Smith pointed out in 1971, this could lead to *E. coli* (which are themselves harmless) being swallowed while swimming and passing on the property of resistance to antibiotics to bacteria in the swimmer's gut.

JOHN NEWELL

BBC, London, UK

The science of astrology?

SIR,—Although one can deplore the mumbo-jumbo of astrology and its patently false postulate that planetary and stellar positions are relevant to the human condition, the condemnation of it in immoderate terms by 186 scientists (September 18) could well prove equally deplorable. It should be remembered that modern chemistry springs from alchemy, beside which astrology seems almost rational!

Perhaps astrology, like alchemy, represents a corpus of observational data collected over millennia which has not yet been codified. It is entirely credible

that a foetus conceived in winter will differ (on account of maternal stress from the environment) from one conceived in summer, and the difference might have behavioural implications. If so, astrology could prove to be a repository of data, access to which is attained by what is virtually an elaborate calendar.

Anthropological or social-science studies along these lines might be profitable; certainly without them outright condemnation is rash.

S. SMITH

Epsom, UK

Botanical decline

SIR,—The declining interest in the botanical sciences is causing concern to biologists, and especially plant scientists all over the world. The implications of declining interest in plants are far reaching, particularly when the need for increasing food supplies becomes more and more urgent. It is therefore of interest to see how the plant sciences are represented in a general science journal such as *Nature*. Without claiming to have made a statistically significant study, I think the following figures are striking indeed, I counted the biologically oriented Letters to *Nature* in 10 recent issues of *Nature*. In 10 issues there were 236 such communications. Of these, 14 dealt with subjects which may be regarded as botanical in the wide sense of the word. Of these 14, two dealt with photosynthesis, three with plant biochemistry and four with fungal metabolism. In other words, the entire area of plant sciences is represented by not quite 6% of the letters to *Nature*. The results of this are of course obvious. Plant scientists being aware of the few botanically oriented articles in *Nature* will respond in two ways. They will tend not to read *Nature*, a fact easily confirmed by casual consultation of colleagues. In addition they will tend not to send papers to *Nature*, because they will readily be overlooked by those most interested.

The existence of fashions in science is well known. What is perhaps not always appreciated is just how invidious the effects of such fashions are. A fashion will lead to increased publication, which in turn draws increasingly the attention of those not working on well defined, clearly oriented problems. Such new criteria as citation indexes aggravate this. One should also

not ignore the repercussions which publication policies have on the availability of research funds. The problem of fashion exists, of course, not only in general science journals but also in specialised ones. Very often the disastrous results are not due to any deliberate editorial policy but to a snowball effect. Articles in a fashionable field will lead to an increasing volume of articles in the same area. It may be assumed that the number of good articles will be greater, the great the number of articles submitted (although this will certainly not be a linear relation). It is then inevitable that articles on fashionable subjects will flood the journals and decrease the interest in less fashionable subjects.

A. M. MAYER

The Hebrew University of Jerusalem, Israel

Cats' eyes: a new twist?

SIR,—Dr Blakemore's work on the rotation of kitten's eyes has—quite rightly—raised a storm of protest and we in the RSPCA are obviously extremely concerned at any suggestion that physical or psychological suffering has been inflicted, to whatever degree.

What also concerns us is that we seem to have yet another example of unnecessary experimentation on living animals. Work by Stratton in 1897 was developed by Snyder and Pronko (1950) and others, leading to that published by Held and Baur in 1967 and subsequently.

It is now well established that no adaption occurs in the primary visual cortex when there is rotation of the visual image; and that visual perception involves the integration of both visual and non-visual activity by the higher centres.

In view of this all that Blakemore seems to have done is to have established that rotation of the retina produces similar effects to those produced by using prisms.

Why does he not admit that this was simply another ill-advised academic exercise instead of attempting 'post hoc' justifications of his 'experiments' on the ground that they will contribute to the treatment of various afflictions which are either incredibly rare, readily studied in humans or both.

D. A. PATERSON

Royal Society for the Prevention of Cruelty to Animals, Sussex, UK

news and views

A TECHNICAL Conference on Tropical Moist Forests (rainforests in the demotic) was to have been held in Brazil this September. The conference, organised by the Food and Agriculture Organization (FAO) of the United Nations, was cancelled in June 1975. With tropical rainforests everywhere under increasing pressure from human activity, this cancellation is doubly unfortunate: on a technical level it retards the dissemination of knowledge, and on a symbolic level it suggests unconcern.

Earlier ecological theory frequently held that complexity, in the sense of many species and a rich web of interlocking relationships, tended to confer stability on a community. More recent work, both empirical and theoretical, suggests that complex ecosystems (of which the rainforest is the archetype) are dynamically fragile. Although well adapted to persist in the relatively predictable environment in which they have evolved, tropical rainforests are likely to be much less resistant to the disturbances wrought by man than are relatively simple and robust temperate ecosystems. Much evidence and thinking in support of this view comes from the report of the (US) Institute of Ecology (TIE) entitled *Fragile Ecosystems: Evaluation of Research and Applications in the Neotropics* (edit. by Farnsworth and Golley, Springer, Berlin, 1974), and from the First International Congress on Ecology held in 1974 (see *Nature*, **251**, 376–377; 1974).

Such generalisations about entire ecosystems can be related to the life history strategies of the constituent species, which may usefully be discussed in terms of the deliberately oversimplified concept of *r* selection and *K* selection. This general notion goes back to Schmalhausen, Simpson, Stebbins and others, but it was MacArthur and Wilson who coined the phrase “*r* and *K* selection”, derived from the conventional parameters in the logistic equation, $dN/dt = rN(1-N/K)$. This equation describes the familiar, sigmoid curve of ultimately bounded population growth: at low population densities, there is essentially pure exponential growth, at the rate *r*; at high densities the population stabilises at a value *K* which is set by the environmental carrying capacity. A *K*-selected organism sees its environment as stable and predictable (and con-

The tropical rainforest

from Robert M. May

sequently the population is usually around its equilibrium value, $N \approx K$). The evolutionary pressures on an organism in these circumstances are, crudely, to be a good competitor; to increase its effective value of *K*; to have fewer offspring but invest more time and energy in raising them. Conversely, an *r*-selected organism sees its environment as unstable and unpredictable (and is usually at low population values, growing exponentially, and undergoing episodes of boom and bust). The evolutionary pressures here are for opportunism; for large *r* to exploit the transient good times; to have many offspring, few of which can expect to mature. Of course, reality is more complicated than this, and the paradigms of *r* and *K* selection are no more than opposite ends of what in fact is a continuum.

Notice that it is difficult to produce extinction in *r*-selected organisms, such as crop pests or the fire ant; their primary adaptation is to bouncing back from low population values. Conversely, *K*-selected organisms are geared to maintain the population around its equilibrium value, and may have difficulty in recovering from a severe disturbance. The extinct passenger pigeon is an example of a once abundant organism of a *K*-selected kind.

Broadly speaking, the contrast between the relatively predictable and stable tropical environment and the relatively vagarious temperate one can be viewed as tending to produce a *K* selection/*r* selection contrast. One manifestation of this is that ecologically analogous animals tend to give birth to fewer progeny in the tropics than in the temperate and boreal zones. Examples are agouti and paca compared with rabbits, peccaries with wild pigs, curassows and guans with pheasants and quails. Lack, Cody and others have presented a wealth of evidence that birds tend to have smaller clutch sizes in the tropics; this and other such data have been reviewed by Southwood *et al.* (*Am. Nat.*, **108**, 791–804; 1974). The overall effect is that tropical animals tend to have less capacity for the sort

of explosive, “pioneer” population growth which characterises their higher-latitude cousins (mythologised by lemmings). They are not well adapted to recovery from bad times.

There is a corresponding tendency to select for competitive ability, rather than weed-like opportunism and adaptability, in tropical plants. One consequence is that seeds tend to have little or no dormancy period, being adjusted to germination in the shady, moist, cool environment of the forest. This is in striking contrast to the wide variety of dormancy periods and survival strategies used by, say, desert plants. Thus, for example, members of the Dipterocarpaceae, the main timbertree family of South-East Asia, have seeds adapted to germinate in the stable microclimate (23–26 °C) of the rainforest soil. Clearing results in severe heating of the soil, and seedling death. The inability of these and many other seeds to recolonise, once sufficiently large areas are disturbed has led Gomez-Pompa *et al.* (*Science*, **177**, 762–765; 1972) to label the tropical rainforest a ‘nonrenewable resource’. Management of rainforests for a sustained yield timber industry is likely to require more sophisticated techniques than for temperate forests, a point underlined in the forestry conference report in *Nature* (**255**, 578; 1975).

Another relevant fact is that the sustained higher temperatures and high humidity in the tropical soil micro-environment makes for much faster decomposition rates than at higher latitudes. The typical turnover time for the decomposition of leaf litter in the tropical rainforest is 6 weeks, compared with 1 year in temperate deciduous forests, 7 years in boreal conifer forests, and 3 years in temperate grassland (Whittaker, *Communities and Ecosystems*, second ed., 248; Macmillan, New York, 1975). Tropical forests tend to respond by storing more of the nutrient pool in the plant biomass, and less in the soil, relative to temperate and boreal forests. This tends to protect lateritic tropical soils from weathering and washout of minerals and nitrates; removal of forests, as in efforts to expand agricultural production, tends to quicken laterisation, which in turn impairs agriculture.

These differences, in the tropics, between soil types which range from volcanic to lateritic, mean that un-

planned land occupation can have unfortunate outcomes. Summarising such problems in South-East Asia, Meijer (*Bioscience*, **23**, 528-533; 1973) has written: "In Vietnam, Thailand, Malaya, Sumatra, Java and the Philippines, only those areas where local agriculture is built around irrigated rice fields can have a stable agriculture and a dense population living in harmony with the environment. The vast hilly sandstone regions of Sumatra and Borneo are not suitable for continuous short-term crops, hill rice or corn; it is, in the long run, economically more productive to keep them as Forest Reserves harvested on a sustained yield basis". Eckholm's review (*Science*, **189**, 764-770; 1975) of the deterioration of mountain environments stresses the consequent effects on the lowlands, and particularly on

tropical lowlands: "The eastward movement of settlers to the jungles of the upper Amazon Basin can appropriately be labelled anarchic.—The frequent result is double disaster: a costly depletion of lumber resources as trees are cleared without regard to the soil's suitability for agriculture, followed shortly thereafter by the abandonment of the unproductive forms".

With most of the Top Ten human population growth rates currently attained in equatorial countries, an acceleration of destructive impacts on tropical rainforests is inevitable. But the long-term effect of this impact could be mitigated by coherent and well informed planning and management. It seems more likely that, in a decade or two, it will be possible to organise a retrospective conference on Tropical Moist Forests. □

Organisation of the mammalian tectum

from Shin-Ho Chung

A NUMBER of recent anatomical and physiological studies on the mammalian tectum (or superior colliculus) provide a glimpse of the ways in which the brain processes sensory inputs to make a final motor command. Axons carrying visual, auditory and somatosensory information converge on the tectum and interlace with tectal neurones, forming an intricate network of nerve cells, the main output of the tectum is then relayed to a number of motor nuclei that control the movement of the eyes or the head towards the source of stimuli. In a sense, the tectum is a microcosm of the entire brain, because it serves as a correlation centre for incoming messages and a command post for eliciting behavioural responses. For this reason, it has fascinated neurobiologists for several decades

In the vertebrates below mammals, the tectal and subtectal areas are the main centres of termination of sensory pathways. In the course of phylogeny, the tectal areas become progressively less important, and some of their functions are assumed by the diencephalon and the cortical centres. The relative size of the tectum is reduced as the diencephalon is enlarged, and this condition becomes progressively more evident from amphibians towards birds and mammals. In all mammals, however, the tectum retains its function of controlling the reflex turning of the head or eyes towards the source of external stimuli.

From the dorsal surface, mammalian tecta appear as a pair of hemispherical bulges in front of the cerebellum. Cell bodies in the tectum are organised into distinctive laminae arranged concentrically around the central grey matter, and each cellular band is separated by a layer of axons originating from

various parts of the brain. Axons stemming directly from the eyes terminate at the most superficial layer of the tectum, with those from the contralateral eye (crossed fibres) positioning slightly more superficially than those from the ipsilateral (uncrossed fibres). Two recent anatomical studies (Graybiel, *Brain Res.*, **96**, 1; 1975; Hubel *et al.*, *ibid.*, **25**) have revealed the intricate pattern by which terminals of optic axons from the two eyes are distributed on the surface of the tectum. The pattern varies systematically as fibres enwrap the tectum from the front to the back. On the posterior half of the tectum, for instance, clusters of uncrossed fibres form regularly spaced terminal arborisations giving the appearance of a chequerboard pattern. Crossed fibres, on the other hand, are distributed as a continuous sheet overlying the terminations of the ipsilateral fibres. The upper margin of this sheet is smooth and well defined, while the lower margin shows regularly spaced indentations interdigitating with the ipsilateral terminals.

Fibres from the visual cortex, which constitute the phylogenetically new secondary visual system, terminate at a slightly deeper level of the tectum, and there link up with the older direct retino-tectal system (Kuypers and Lawrence, *Brain Res.*, **4**, 151; 1967; Kawamura *et al.*, *J. comp. Neurol.*, **158**, 339; 1974). Although the mode of synaptic terminations of the direct and indirect visual fibres on tectal cells has not been clearly elucidated, it is known that a single tectal cell sometimes receives inputs from both sources (Sterling, *Vis. Res.*, **11**, 309, 1971; Hoffman, *J. Neurophysiol.*, **36**, 409, 1973)

In addition to the visual inputs, the

tectum receives projections from other sensory modalities, mainly the auditory, proprioceptive and somatosensory systems. These inputs originate from various parts of the brain, including the inferior colliculus (Powell and Hatton, *J. comp. Neurol.*, **136**, 183; 1969), auditory cortex (Garey *et al.*, *J. Neurol. Neurosurg. Psychiatry*, **31**, 135; 1968), spinal cord (Mehler, *Ann. N. Y. Acad. Sci.*, **167**, 424; 1969) and motor cortex (Sprague, *Anat. Rec.*, **145**, 288; 1963), and terminate at the deep layers of the tectum. Tectal neurones appear to form a synaptic chain, with superficially located cells synapsing onto successively deeper ones. At each level, extrinsic afferent fibres make further synapses with this intrinsic chain of neurones (Sprague, *Neurosci. Res. Prog. Bull.*, **13**, 204; 1975). The main output of the tectum is then channelled into the two motor nuclei (the Interstitial Nucleus of Ramon y Cajal and the Nucleus of Darkshevitich) and certain parts of the spinal cord that control eye and neck movements (Altman and Carpenter, *J. comp. Neurol.*, **116**, 157; 1961).

These anatomical descriptions accord with physiological studies. Cells in the superficial layers of the tectum have small visual receptive fields, responding optimally to a moving stimulus. Other cells, probably located slightly deeper than these simple cells, show several added complexities in their response pattern. For example, they show preference for a particular direction of movement, discharging briskly only when the visual stimulus is moving in a certain direction. After destruction of the visual cortex, this feature is seldom found, thus indicating that the cortical connections are responsible for this complexity (Wickelgren and Sterling, *J. Neurophysiol.*, **32**, 16; 1969; Rosenquist and Palmer, *Expl Neurol.*, **33**, 629; 1971; Berman and Cynader, *J. Physiol., Lond.*, **245**, 261; 1975). There is a marked increase in the size of receptive fields with increasing depth in the tectum, and cells in the deep layers respond to visual as well as somatosensory and auditory stimuli (Cynader and Berman, *J. Neurophysiol.*, **35**, 187; 1972).

Not only are the inputs to the tectum organised in laminae, they are also topographically ordered with respect to the external world, so that all the cells in a given column attend to the same part of the environment. Gordon, *Science*, **173**, 69; 1971; *J. Neurophysiol.*, **36**, 157; 1973) first showed that the optimum position of a sound source relative to the animal's head, for eliciting responses from a particular part of the tectum, corresponds with the positions of visual receptive fields of cells in the same part of the tectum. Moreover, if a

visual cell shows a particular preference for a given direction of movement, the deeper tectal cell responds best to a sound source moving in that direction. The columnar overlap of different sensory modalities has recently been re-examined (Dräger and Hubel, *Nature*, **253**, 203; 1975; *J. Neurophysiol.*, **38**, 690; 1975; Stein *et al.*, *Science*, **189**, 224; 1975). In both the cat and mouse, the map of the visual space is topographically coincident with the somatosensory representation of the animal's body. In the mouse, protruding whiskers cover the major part of the visual field. A tectal cell responding to gentle tapping of a whisker lies below a visual cell looking at that whisker. In those parts of the tectum involved in the visual field where no whiskers are in the way, somatosensory responses at deep levels are elicited from other parts of the body. For instance, inferior visual fields where the mouse may see its own paw are associated with tactile fields on the paw. The output of the tectum is then somehow coupled to the motor system such that the animal brings the source of stimuli into its central visual field. This has been demonstrated by directly stimulating different parts of the tectum electrically (Schiller and Stryker, *J. Neurophysiol.*, **35**, 915; 1972).

The hierarchical organisation of nerve cells, as found in the mammalian tectum, is the general principle on which all nervous systems are constructed. At each successive level, incoming messages are further processed, and the stimulus features to which a neurone will respond become more specified. Elucidating the rules whereby important features of the external world are extracted and recombined by the nervous system has been one of the fundamental problems in neurobiology. It is toward this aim that a group of neurobiologists are gradually building up the basic 'wiring diagram' of the tectum. What developmental mechanisms ensure the formation of such an exquisitely ordered structure are likely to remain unknown for a long time. □

Host selection by a parasitic mite

from F. E. G. Cox

MANY parasites make use of chemical signals to identify suitable hosts but in few cases have either the nature or the sequence of these signals been characterised. Arthropods usually exhibit a two-stage pattern of behaviour in which they first search for their hosts and then orientate themselves with respect to chemical stimuli emanating therefrom. Most studies on host finding have been based on insects such as

A hundred years ago

WE have received an address by Prof. R. H. Thurston, C.E., delivered to the graduating class of the Stevens Institute of Technology (U.S.). It is entitled "The Mechanical Engineer, his Preparation and his Work," and contains some excellent advice, useful not only to young engineers, but to all who have been trained to other mechanical professions. The Stevens Institute, though what we would call a technical college, affords a good general scientific training, with a fair admixture of literary culture, and the object of Prof. Thurston's address is to show that the more complete is the culture of an engineer, the greater is likely to be his professional success.

from *Nature*, **13**, 16; Nov. 4, 1875

mosquitoes that attack man (see for example Gillies and Wilkes, *Nature*, **252**, 388; 1974) but in this issue of *Nature* (page 788) Egan, Barth and Hanson describe how a mite that parasitises cockroaches locates and identifies its host. These authors used simple two-choice preferential tests and the attractant substances were applied to paper disks under controlled conditions. In all, the responses of 12,000 mites were examined. In itself, this study has little practical application in the immediate future, but it opens up possibilities of analysing the factors that cause mites to attack man and his domesticated animals and the development of methods of protection against these ectoparasites and the diseases they transmit.

The mite used was *Proctolaelaps nauphoetae* which is specific to and gregarious on the cockroach *Nauphoeta cinerea*. *P. nauphoetae* is first attracted to faecal materials and the sorts of things that occur in cockroach nests, such as pieces of limbs and rotting organic material. The identification and orientation towards such materials is likely to bring the mites to a cockroach nest, and it was confirmed that they can recognise nest "markers" because they preferentially seek out individuals that have been living in colonies, in contrast to those of the same species that have been living alone, and they are also attracted to non-host species that have been placed in host colonies.

Having come into the proximity of a cockroach colony, a second level of attraction enables the mites to identify cockroaches belonging to the same family as the host and to avoid others. The attractant consists of the expectorants which are spread over the body during grooming. The mite has then

to determine whether or not the cockroach is the appropriate host species. The actual substance that is used was isolated by placing paper disks in the colony and extracting the attractant from them. The authors tentatively identify this substance as a poly-amino sugar and call it "nauphoetamine". The identification of "nauphoetamine" by the mite is the final stage of the host-finding behaviour but it is important to note that chemical stimuli are involved in the first two stages: the recognition of the proximity of any kind of colonial cockroaches by faecal and detritus stimuli, and direct orientation to expectorants which brings the mite to a particular group of cockroaches which might or might not be the correct host species.

The fact that the mites show three separate levels of discrimination and that one at least of the attractants can be isolated means that it should be possible to attract mites away from potential hosts or towards pest species if biological control is the aim. Even if these studies do not lead to any further progress in the manipulation of mites they will be of general interest to parasitologists in several areas where host finding and identification are poorly understood and at present, in the case of warm blooded animals, often simply attributed to host temperature. □

Is submicrominiature small enough?

from Andrew Holmes-Siedle

SOLID-state science has made it possible to put all the circuits of a computer onto a piece of silicon no larger than a postage stamp (say 1 cm² in area). It is reasonable to ask how much further one should try to go. Should we now put the computer onto a pinhead or put a faster, more versatile computer with much more storage onto the same square centimetre? The idea has its attractions because we are never short of information to process (visual information flows in on us at more than 10 million bits per second, for example), and it saves energy if we cut down the amount of purified electronic material needed to make the circuits.

Two authoritative surveys on the ultimate limits to the density of electronic functions on a wafer of electronic material have appeared recently. One, by J. T. Wallmark (*Institute of Physics Conf. Ser.* No. 25, 133; 1975), starts from the practical necessities of integrated-circuit technology and, through original calculations, reaches quantitative conclusions. The other, by R. W. Keyes of IBM Research Centre (*Proc. IEEE*, **63**, 740; 1975) starts from some basic laws of device physics, collects results of many other workers and produces a set of conceptual tools rather

Comparison of physical limits in digital electronics

	Mathematical symbol	Units	Typical 1965 circuit	Typical 1975 circuit	Wallmark's ultimate circuit	Ultimate if pattern generation were only factor	Human brain
Number of transistors or other active elements	N		10	10^4	10^6	2.5×10^9	10^{10}
Linear dimension of chip	$\sqrt{A_c}$	μm	6.6×10^3 (0.66 cm)	10^4 (1 cm)	6.6×10^3 (0.66 cm)	10^4 (1 cm)	—
Area of chip	A_c	μm^2	4×10^7	10^8	4×10^7	10^8	—
Area per active element with allowance for interconnections	A_c/N	μm^2	4×10^6	10^4	4×10^3	4×10^{-2}	—
Side of active element (e.g. whole transistors)	$\sqrt{A_c/N}$	μm	2×10^3	10^2	20	2×10^{-1}	4
Linewidth, d , required to fabricate element	$10^{-1}\sqrt{A_c/N}$	μm	200	10	2	2×10^{-2}	—
Minimum edge uncertainty, ΔL , for above linewidth	$5 \times 10^{-4}\sqrt{A_c/N}$	μm	1	5×10^{-2}	10^{-2}	10^{-4}	—
Wavelength of light required	$2\Delta L$	μm	2	0.1	2×10^{-2}	—	—
Energy of electron beam required	$2h^2/m\Delta L^2$	eV	$\ll 1$	< 1	~ 0.1	100	—

than quantitative conclusions. The two are thus complementary, and provide a good foundation for the statement that we cannot much longer continue the trend by which the density of devices per unit area is doubled annually. Physical laws will in fact soon prevent us. The limiting processes include the propagation of light, thermal conduction, electromigration and dielectric breakdown. The first three columns of the table, derived loosely from Wallmark's and Keyes' formulae, show where the downward trend in size must stop. While, in the past ten years, the area of an active, multielement structure such as a transistor has gone down from about 1 mm^2 to 0.01 mm^2 , giving a minimum element width, d , of $10 \mu\text{m}$, Wallmark gives good arguments as to why it can never go lower than $2 \mu\text{m}$. One major problem, very difficult to circumvent, is that the local concentration of doping impurity atoms fluctuates noticeably on this scale so that small elements such as resistors, intended to be of the same value, will in fact fluctuate in value. Wallmark is alone in seeing this as the main physical barrier, but both authors find that active devices, such as transistors can only pass a certain current density before breakdown phenomena occur, and the size limit for this effect again occurs when d is a few micrometres.

It is worth noting that the technology for making linewidths much smaller than $2 \mu\text{m}$ is well in hand. While conventional ultraviolet light cannot be used near Wallmark's limit (see table), the wavelengths of low-energy electron beams are such that much smaller patterns could be made with ease. I would estimate that, if pattern generating were the only limit, one could fit more than 10^9 transistors on a chip of area 1 cm^2 (see fourth column of table), but electrical breakdown, heating and electromigration effects would attend the high current densities and electric fields which these much smaller elements would experience. The reason why fields increase as size decreases stems from the existence of voltage noise. Random voltage fluctuations of value kT (0.025 eV at 300 K) occur across

junctions and the applied voltages must swamp these. Thus, voltage cannot be scaled down with element size. Keyes further insists that, with all digital logic devices, the mode of operation must be such that large non-linearities in the I-V characteristics are involved. This requires operating voltages of 10 – 100 times kT . In non-digital systems, however, smaller energy transfers can possibly be used to process information. Keyes gives an interesting study of the bare essentials of a logic operation, namely two potential wells with a small barrier between them, the barrier being of the order of kT . In the ideal case, the energy dissipated in one operation of this system is of the order 10^{-21} J at 300 K and this is the quantum limit. By contrast, low-power logic uses about 10^{-10} J per operation. The only known information-processing system which approaches this efficiency is a natural one—the passage of information during nucleic acid transcription, which involves about 10^{-19} J per operation. The advantage which nature has here is that speed of processing is of little importance to cell growth. The human brain, requiring greater speed of operation, operates at about the same energy per operation as low-power electronic logic.

A difference in conclusions on minimum size, as reached by Keyes, Wallmark and another earlier study (Honeisen and Mead, *Solid St. Electron.*, **15**, 819, 891; 1972) lies mainly in their ideas of which elements of the circuit will in future be the controlling ones. For this, Keyes chooses the interconnections between devices, in which the speed of light will limit speed of transport and high current densities can produce heating and electromigration (minimum linewidth, $10^{-1} \mu\text{m}$). Honeisen and Mead see dielectric breakdown as an earlier barrier (minimum width, $1 \mu\text{m}$) while, as mentioned, Wallmark takes the broader view and considers that the statistics of pattern generation (not fully considered by the others) and doping fluctuations will raise the limiting width well above $1 \mu\text{m}$. Agreement on the minimum power dissipated for a given speed of

operation is fairly good. At room temperature, voltage fluctuations and the capacitances of components will not allow speeds of operation faster than a few tenths of a nanosecond or power levels below a nanowatt per element. In special cases, cooling to cryogenic temperatures can lead to lower power levels, although commonsense suggests that almost all the uses for the most minute logic devices will tolerate neither the inconvenience nor the power drain involved in continuous cooling. It seems that, unless we can develop some very unusual electronic materials, the only way to encompass extremely small size in computers is to accept a slower-than-normal rate of operation. Furthermore, we might as well accept that we will never get the equivalent of a videotape recorder or Atlas computer which will fit comfortably in the pocket.

Hormonal regulation of hormone receptors

from J. R. Tata

THE central issue in research on hormone action is a better understanding of hormone-receptor interaction. Until recently, kinetic analyses of hormone receptor function have been based on the assumption that the number of receptor sites per target cell is constant, or that its fluctuations are of little physiological consequence, so that what really matters is the number of hormone molecules that are available for interaction with receptor sites. Reports are, however, now trickling in to suggest that the number of receptors per cell can vary sufficiently to influence the response of the target cell to the hormone. What renders this idea particularly intriguing is the possibility that a hormone can modulate the cellular level of its own receptor or that of another hormone.

Hinkle and Tashjian, Jr. (*Biochemistry*, **14**, 3845; 1975) have recently examined the effect of thyrotropin-releasing hormone (TRH), a hypothalamic tripeptide, on the number of

receptors for this hormone in a clonal strain of rat pituitary tumour cells (GH₃ cells). These cells do not make thyrotropin (TSH) but TRH does stimulate the synthesis and release of the hormone prolactin and inhibits the formation of growth hormone by these cells. Previously it had been shown that TRH bound firmly to GH₃ cells, presumably to receptors on plasma membranes of the type found in normal pituitaries (Vale *et al.*, *Endocrinology*, **93**, 26; 1973; Gourdji, *et al.*, *Expl Cell Res.*, **82**, 39; 1973) and that the binding preceded the action of the hormone. According to Hinkle and Tashjian, incubation of GH₃ cells for 2–3 days with TRH caused a reduction in the number of binding sites for TRH to a third of the normal level. Receptor molecules seem to be long-lived and their loss itself requires active protein synthesis since cycloheximide protects the cells against receptor depletion. A consequence of such a hormone-induced loss in receptor capacity would be that it would provide a target cell with the means to regulate its sensitivity to the hormone.

Is the above example of a hormone regulating the number of its own receptor molecules a peculiarity of abnormal tumour cells or of culture conditions, or does it reflect a universal physiological homeostatic mechanism for hormones? After all, GH₃ cells do not synthesise TSH whereas the action of TRH on normal pituitary cells is to control their TSH output. In another pituitary tumour cell line, GH₁ cells, whose growth is influenced by thyroid hormone, Samuels and Tsai reported that tri-iodothyronine (T₃) increased the number of T₃ receptors in the nucleus (*Proc. natn. Acad. Sci. U.S.A.*, **70**, 3488; 1973). But, Spindler *et al.* (*J. biol. Chem.*, **250**, 4113; 1975) have failed to observe a similar phenomenon for the number of T₃ receptors in normal rat liver nuclei. It may, therefore, be premature to generalise about the self-regulation of hormone receptors. Perhaps one needs to examine those systems where sensitivity of a tissue to a hormone changes very rapidly, as during ontogenesis or during certain hormone-dependent cyclical physiological situations. It may well be that the basis of the "positive feedback" phenomenon during amphibian metamorphosis may be due to marked changes in the number of T₃ receptors in the tadpole hypothalamus. Similarly, oestrogenic hormones regulating the level of their own receptors may underlie the cyclical variations in the hormonal sensitivity of the uterus during the oestrus cycle. In this context, an interesting example of induction of oestrogen receptor by oestradiol was reported by Gschwendt and Kittstein (*Biochim. biophys. Acta*, **361**, 84;

Eruption anticipated

from Peter J. Smith

ON July 5–6 this year the Hawaiian shield volcano, Mauna Loa, erupted for the first time in 25 years. The renewed activity was not entirely unexpected, however, for only a few weeks before the eruption scientists at the US Geological Survey's Hawaiian Volcano Observatory had prepared a report, based on seismic and geodetic data, suggesting that Mauna Loa "may be reawakening". As it turned out, the report was overtaken in press by the event, but now that it has been published (Koyanagi *et al.*, *Geophys. Res. Lett.*, **2**, 405; 1975) it is possible to see the evidence upon which the prediction was based.

Since Mauna Loa last erupted in 1950, seismic activity in its vicinity has been low but not completely absent. Records covering the past 13 years show that there were several bursts of activity which reached small peaks in 1962, 1967 and 1970, each larger than the one before. But in April 1974 the frequency of small summit earthquakes increased con-

spicuously, reaching hundreds to thousands a day for a week in mid-August, more than a week in mid-December and for many days between February and June 1975. Throughout the whole period 1962–1975 magnitudes ranged up to 4.6 but most of the events with magnitudes greater than 3 occurred during 1974–75.

During the latter period the shocks generally became not only larger but also shallower than before. Most of the foci were at depths of less than 15 km, although a few reached 50 km. Moreover, there was an earthquake-free zone at depths of 15–30 km beneath the summit crater, believed to indicate a magma storage region. The epicentres defined a broad seismic zone around the summit where dilation was evidently also occurring. Thus geodimeter measurements showed that a 2.5 km line across the summit caldera expanded by 10 cm between August 1974 and June 1975.

Taken together, these data strongly indicated a resumption of volcanic activity, although they were far from sufficient to enable the time of any eruption to be predicted.

1974). These workers demonstrated that injection of oestradiol to male chicken leads to the induction of high affinity nuclear binding sites (K_D of about 10^{-9} M) in the liver under conditions in which the hormone induces the synthesis of egg-yolk proteins in this tissue.

Perhaps a more common situation in which hormonal modulation of hormone receptor level may have physiological relevance is that in which one hormone controls the level of receptors for another hormone. Several complex, multi-hormone systems are known whereby one hormone conditions a tissue or a group of cells in its response to another. Two examples of such hormonal interplay are lactation, in which steroid hormones induce the mammary epithelial cells to become sensitive to the lactogenic hormone, prolactin (see Topper, *Recent Prog. in Hormone Res.*, **26**, 287; 1970) and the sensitivity of the chick oviduct to progesterone being dependent on previous stimulation by oestradiol (see O'Malley *et al.*, *Recent Progr. in Hormone Res.*, **25**, 105; 1969). It is therefore of some interest that oestrogen induces a cytoplasmic 7S receptor for progesterone both in the chick oviduct (Toft and O'Malley, *Endocrinology*, **90**, 1041; 1972) as well as in the hamster uterus (Reel and Shih, *Acta Endocr.*, **90**, 344; 1975). With interest in the above phenomena increasing rapidly, it is safe to predict that many "hormone receptorology" papers will be dealing with the regulation of hormone

receptor levels. Whatever the outcome of such efforts, the important issue will still be the perennial question of how does one equate hormone binding with the site, or sites, of relevant physiological actions of a given hormone.

A most Friendly meeting

from Natalie Teich and Paul Harrison

The Friend Cell Workshop was held at Schloss Reisenburg, West Germany, on August 28–September 1.

THE workshop established the relevance of the Friend virus–Friend cell system as a model for erythropoietic differentiation, for multiple host gene control of erythroblastic disease and for studies of the relationship between cell transformation and abnormal differentiation.

The cell biology of the Friend cell system was a major topic. Friend virus (FV) infection of susceptible mice results in enhanced erythroblastosis and polycythemia or anaemia (the original virus strain of Dr C. Friend) due to massive cell death in the early erythroblast compartment (C. Jasmin, Hôpital Paul Brose, Villejuif). It now seems established that the target cell for FV is a committed erythroid stem cell (CFU-E) (P. Tambourin, Radium Institute, Paris) Axelrad's group (Uni-

versity of Toronto) have isolated a strain of virus able to transform normal CFU-Es *in vitro* as judged by their ability to differentiate without erythropoietin. This may be analogous to the *in vitro* transformation of avian bone marrow cells by avian erythroblastosis virus (AEV) (T. Graf, Max-Planck-Institut, Tübingen).

A diversity of studies have evolved from the isolation of Friend erythroleukaemic cells (FLC) *in vitro* (C. Friend, Mount Sinai School of Medicine, New York). These cells are CFU-Es arrested at the proerythroblast stage, which after treatment with dimethylsulphoxide (DMSO) synthesise haemoglobin and differentiate to orthochromatic erythroblasts and possibly further (Y. Ikawa, Cancer Research Foundation, Tokyo). Other erythroid changes follow: spectrin formation and loss of H-2 surface antigen (H. Eisen, University of Geneva) and accumulation of carbonic anhydrase (F. Ruddle, Yale University). New compounds, such as highly polar molecules and fatty acids (R. Rifkind and P. Marks, Columbia University, New York) also act as inducers; haem also can induce globin synthesis and may act synergistically with DMSO (J. Ross, McArdle Laboratory, Wisconsin; A. Beaudet, Baylor College, Houston). This induction of erythroid differentiation in FLC contrasts with the situation in AEV-transformed avian erythroid cells which do not differentiate or produce haemoglobin in response to classical inducers of FLC (Graf), although they accumulate globin RNA in the nucleus (A. Therwath, University of Paris).

Little is known concerning the mechanisms of action of the various inducing agents. Membrane function may be important, however. A. Bernstein (Ontario Cancer Institute, Toronto) found that local anaesthetics which increase membrane fluidity block haemoglobin production. This is consistent with other membrane changes including rapid immunological "capping" (N. Furusawa, Osaka City University), increased agglutination with plant lectins (Eisen), decreased permeability to small molecules (S. Dube, California Institute of Technology), increased anisotropy (D. Jovin, Max-Planck-Institut, Göttingen) and changes in cyclic nucleotides (R. Kram and P. Malpoix, University of Brussels).

Regarding the cell cycle dependence of the induction process, haemoglobin is not detectable until cells have been exposed to DMSO for about two cell cycles (J. Papaconstantinou, Oak Ridge National Laboratory; Marks and Rifkind). However, J. Pragnell (Beatson Institute, Glasgow) and W. Ostertag (Max-Planck-Institut, Göttingen) reported that one FLC line shows

a 5-fold increase in globin mRNA within the first cell doubling.

Several laboratories have attempted to elucidate the mechanisms regulating globin gene expression in FLC, exploiting DNA complementary to globin mRNA to measure synthesis and accumulation of globin-specific RNA. H. Aviv (Weizmann Institute, Rehovoth) stressed that relative rates of degradation of globin and total mRNAs are important in understanding how globin mRNAs predominate in the reticulocyte or differentiated FLC. Unfortunately even the sensitive techniques used are insufficient to permit similar analyses at the nuclear level to clarify the role of transcriptional and post-transcriptional regulation mechanisms. The fact that the base-sequence complexity of poly(A)-containing nuclear RNA is considerably greater than that of polysomal poly(A)-containing RNA indicates post-transcriptional control of gene activity (M. Birnie and J. Paul, Beatson Institute, Glasgow).

Another approach to regulatory mechanisms was described by P. Harrison and D. Conkie (Beatson Institute) utilising non-inducible FLC variants. In some, non-inducibility of globin synthesis is due to a dominant

defect at the nuclear level (either in globin gene transcription or an unstable primary RNA transcript); whereas in another, treatment with haem enhances globin and globin mRNA accumulation. Interestingly, in a lymphoma \times FLC hybrid, globin mRNA accumulates, but globin chains do not; nor does erythroid maturation occur unless the hybrid cells are treated with haem in addition to DMSO. A regulatory role for haem in differentiation of FLC is also implied by the report of G. Kramer and B. Hardesty (University of Austin, Texas) that there are two inhibitors of translation in Friend cells, one of which is present in DMSO-treated cells only and bears close similarity to the classical haemin-controlled repressor present in reticulocytes.

Others are also using cell fusion to analyse the regulation of differentiation. B. Alter (Childrens Hospital, Boston) showed that some human globins were synthesised in heterokaryons between tetraploid FLC and diploid human amniotic fibroblasts but not in hybrids with diploid FLC. A. Skoultschi (Albert Einstein, New York) observed that hybrids between FLC and mouse hepatoma cells continue to synthesise albumin and transferrin but cannot be induced to synthesise haemoglobin or globin mRNAs. The potential of somatic cell genetics for genetic mapping was illustrated by A. Deisseroth (National Institutes of Health) by exploiting stable mouse-human hybrid clones to correlate loss of human globin genes with loss of specific chromosomes. It should only be a matter of months before the location of the α and β genes are known with certainty.

As regards the virus-host interactions, it is clear that at least three genes of the mouse determine the course of the erythroblastic disease induced by FV. The *Fv-1* locus controls the ability of the helper murine leukaemia virus (MLV) component to initiate productive infection. A second gene, *Fv-2*, controls the animal's response to the spleen focus-forming element (SFFV) of FV; in a resistant mouse, MLV and SFFV replicate and although morphologically distinct spleen foci do not appear, splenomegaly occurs later (5 weeks) (T. Odaka, Institute of Medical Science, Tokyo). K. Blank (Albert Einstein, New York) showed the restrictive effect of each locus not only on the spleen focus formation but also on the ability of the animal to limit growth of the tumour colony-forming cells. A third locus, the major histocompatibility locus (*H-2*), seems to affect not the initial infection by FV, but rather the subsequent ability to support chronic infection (H. Freedman, Albert Einstein,

Chemical and biological reactions

IN my recent comments (*Nature*, 256, 693; 1975) on dynamics of chemical and biological reactions I mentioned work by Uzgis and Golibersuch (*Phys. Rev. Lett.*, 32, 37; 1974) attributing a decay term independent of scattering angle in scattered-light intensity fluctuations from haemoglobin solutions to the haemoglobin association-dissociation reaction. A paper by Haas, Mustacich, Smith and Ware (*Biochem. biophys. Res. Commun.*, 59, 174; 1974) which disputes these findings has now come to my attention. These authors attribute the "anomalous" positive intercepts in the plot of linewidth *versus* the square of the scattering vector reported by other authors to the coincidence of the Helium-Neon wavelength and the 630 nm absorption of methaemoglobin. I am bringing these findings to the attention of your readers in view of the importance of establishing whether reaction rate of fast chemical and biological reaction can be derived from time autocorrelation functions.

I would also like to state that the fluorescence of ethidium bromide is strongly enhanced, and not quenched (as mentioned in my comments) upon binding to DNA.

H. EISENBERG

New York). G. Hunsmann (Tumor Immunology, Freiburg) reported that FLC express viral surface antigens gp71 and p12; further, immunisation either with gp71 or antiserum to gp71 will protect animals from FV disease.

Ostertag showed that treatment of FLC with BUdR and DMSO often leads to the induction of endogenous viral genomes, thus complicating the host range patterns of the Friend virus complex. Pragnell reported that sequences present in Friend virus released from DMSO-treated FLC are integrated 5-10 times in Friend cell DNA; whereas about half of these sequences (SFFV?) are absent in mouse embryo DNA. Ostertag and P. Swetley (Boehringer Institute, Vienna), as well as Ruddle, have shown that interferon treatment will effectively block virus replication without inhibiting haemoglobin synthesis. Other agents such as azidothymidine act similarly. Ostertag does, however, find a correlation between induction of differentiation and increase in intracisternal A-type particles.

N. Kluge (Max-Planck-Institut, Göttingen) and Sugiyama have established several rat erythroleukaemia lines by treating animals with dimethyl benzanthracene; these lines are induced for haemoglobin synthesis with DMSO and for virus production with BUdR. B. Weimann's (Immunology Institute, Basel) human polycythemia vera lines are not responsive to erythropoietin, but A-type particles are seen after treatment with azidothymidine. Thus, the Friend cell phenomenon is not restricted to the mouse. □

Man-made earthquakes

from E. Nyland and D. I. Gough

The first International Symposium on Induced Seismicity (ISIS) was held in Banff, Alberta, Canada, from September 15 to 19. ISIS was organised as a consequence of the Conference on Seismic Effects of Reservoir Impounding held in London in 1973, and both were instigated and supported by a working group of UNESCO. ISIS was additionally supported by the Government of Canada and was organised from the Universities of Alberta and British Columbia. The Proceedings of ISIS will appear late in 1976 in *Engineering Geology*.

AMONG engineering activities which have inadvertently produced earthquakes are the building of dams which

form large reservoirs, the injection of water into crustal rocks for waste disposal or oil extraction, and deep mining. All three topics were actively discussed, although the bulk of the papers were concerned with reservoir-triggered earthquakes.

D. W. Simpson (Lamont Doherty Geological Observatory, New York) led the papers on this topic with a comprehensive review of large reservoirs, only a small fraction of which are known to have triggered seismic activity. Among the contributed papers was one by O. V. Soboleva and colleagues (Academy of Science, Padzhik SSR), presented by Simpson who is visiting Dushanbe, USSR on a US/USSR collaborative project on detailed studies of seismicity induced by Nurek Reservoir, formed by the world's highest earth-fill dam. Epicentres migrated to the southwest end of the lake from a distance of 8 km over the years 1971-74. Focal mechanisms are complex. Six seismologists and engineers from the People's Republic of China reported on admirably thorough studies of the intense seismic activity induced by the Hsinfengkiang reservoir, where some quarter million seismic events have been detected since the lake began to fill. At least four mechanisms have been involved: initial normal faulting may have been load-induced and facilitated entry of water to deeper foci for larger subsequent strike-slip events. Another major field study, this time of the Tarbela dam in a region of very high natural seismicity in the Pakistani Himalayan foothills, was reported by Klaus Jacob (Lamont Doherty). Current discussions of earthquake control by fluid injection lend interest to a paper by C. G. Bufe (US Geological Survey) reporting a gap in seismicity on the Calaveras Fault in California: the gap is near the small Anderson Reservoir and elsewhere there are many events along the fault.

A few generalisations can be stated. Initial stress is clearly a principal factor in the triggering of earthquakes by reservoirs, but techniques for its measurement remain costly and of doubtful generality. They are almost never applied except near the dam itself. Fluid pressure is probably the main triggering mechanism, although incremental solid stress can serve where normal faults are critically prestressed. In the largest earthquakes triggered by reservoirs (Kremasta, Kariba, Koyna, Hsinfengkiang) magnitudes of mainshocks do not exceed 6.3, an empirical observation which may be related to the rock volume affected by very large reservoirs.

Carl K. R. Ling (Cooperatives Institute Research in Environmental Sciences, Boulder, Colorado) gave a review of theory of induced seismicity, which

finds its basis in the principle of effective stress in a porous water-filled medium and Coulomb-Mohr shear failure criteria. The extensions of these simple notions to real permeable formations has become immensely complicated. The following session showed encouraging moves toward an attack upon calculation of stress fields in porous, fractured media. Tidal triggering seems possible under at least one reservoir.

A session on mechanical and hydraulic properties of rocks related to induced seismicity was led by P. A. Witherspoon (University of California, Berkeley) with a survey of a vast body of results from his laboratory. Contributed papers considered properties of fractures, friction and sliding in rocks.

Seismicity associated with deep mining differs from induced seismicity of other types in that the excavation can itself produce stress-differences sufficient for failure, so that the effect need not, in all cases, be a triggering: initial stress may thus be lithostatic. Another special feature of this class of event is that the focal region can be visited and studied before and after the shock. A review of many years' study in Witwatersrand gold mines was given by N. G. W. Cook (Chamber Mines, South Africa). A feature of work in the central Witwatersrand is the extreme dryness of the rock there. Contributed papers included discussions of seisms produced by longwall coal mining in the United States and of seismic efficiency of mine tremors in the Witwatersrand. An earthquake sequence triggered by unloading of rock from a quarry in the Hudson valley is really explained in terms of thrust-faulting mechanisms and reduction of the vertical (least principal) stress.

A swarm of earthquakes about 10 km from a reservoir several years old, near Oroville, California, is following a mainshock on August 1, 1975. The timing was excellent in relation to ISIS, and an evening session was organised by Lloyd Cluff (Woodward-Clyde Consultants, Oakland, California). Studies by his consultant group, by the US Geological Survey and by the University of Nevada contributed to a fascinating case-history but leave unanswered the question whether the reservoir induced the earthquakes, which occurred on an active fault.

J. H. Healy (US Geological Survey) led a session on seismicity associated with fluid injection with a lucid review of results from the US Geological Survey investigations into the Denver earthquakes and the Rangely Oilfield earthquakes, both in Colorado. His was perhaps the most up-to-date review, being completed on the morning of the

session. In contributed papers there were discussions of seismicity related to hydraulic mining in New York state and seismicity associated with a complex of oil, water and gas at different levels under Lacq, France.

In seismicity related to fluid injection, fluid pressure is clearly the trigger and as with reservoirs, the pre-existing fractures and stresses are all-important and in general only become known if and when earthquakes occur. Pulling the trigger is not the best way to find out whether a gun is loaded; measurement of initial stress near future reservoirs and near oilfields where high-pressure injection is proposed could be a useful exercise for government agencies.

A session on instrumentation for observation of induced seismicity was led by a review by E. R. Kanasevich (University of Alberta), who made a strong case for introduction of digital recording systems employing miniaturised solid-state electronics and dedicated minicomputers. This triggered a brisk discussion in which the merits of many simple instruments were urged by others, particularly in adverse environments far from shop support.

The six review papers and over fifty contributed papers provoked lively and absorbing discussions and it is a matter of regret that more seismologists, and especially more engineers, did not attend. For those who did, the week seems to have been well spent. □

Growth hormone at Milan

from Mike Wallis

The Third International Symposium on Growth Hormone and Related Peptides was held in Milan on September 17–20. Abstracts have been published (*Ricerca Scientifica ed Educazione Permanente*, 2, Suppl. 1) and the invited lectures will be published in full by *Excerpta Medica* in 1976.

PROTEINS come in families, and this conference covered all the members of the pituitary growth hormone family, including prolactin and placental lactogen. The ground covered was thus broad (over 160 papers) and attention here will be concentrated on growth hormone (GH).

A topic which raised much discussion was the possibility that pituitary GH itself is in fact a prohormone. S. Ellis and R. E. Grindeland (NASA-Ames Research Centre, California) described studies on the nature of GH in human

plasma, and concluded that the circulating form has enhanced biological activity and reduced immunological activity compared with GH extracted from pituitaries; purification of GH from plasma is underway. U. J. Lewis *et al.* (Scripps Clinic, La Jolla) have detected various forms of GH (apparently produced by limited proteolytic cleavage) with enhanced biological activities; these are obviously candidates for the 'activated' form which appears to circulate in the blood. M. A. Vodian and C. S. Nicoll (University of California) found that bioassay and immunoassay gave widely differing results for circulating GH in the rat (and for GH secreted by pituitaries incubated *in vitro*) although the two assays agree well when used to measure the GH content in the pituitary of resting, untreated rats.

The suggestion that GH is modified *in vivo* accords well with observations that active fragments can be produced by limited proteolysis of the hormone *in vitro*. C. H. Li and T. A. Bewley (University of California) and J. L. Kostyo *et al.* (Emory University) described the characterisation of peptides from plasmin digests of GH which retain biological activity in several different assay systems. L. Graf *et al.* (Research Institute for Pharmaceutical Chemistry, Budapest) described a similar approach using thrombin. Active fragments have also been synthesised chemically, as described by F. Chillemi *et al.* (University of Milan). How these studies on active fragments produced *in vitro* can be related to those produced *in vivo* is not yet clear. One attempt to make the link has been made by J. Bornstein (Monash University) who has isolated (from pituitaries) small peptides apparently derived from growth hormone. These have been synthesised chemically, and have been shown to be active in a range of pharmacological and biochemical test systems, but how they relate to the other work on GH fragments, or to the major biological actions of GH, remains uncertain.

Biosynthetic precursors of GH have been suggested on several occasions, and a paper by F. C. Bancroft (Columbia University) provided an elegant demonstration of the probable existence of such a precursor. Messenger RNA (from a line of pituitary tumour cells) was prepared and translated in a cell-free system from wheat germ. A major product possessed immunological and chemical resemblance to GH, but was 20% larger than the normal hormone. It appears that the wheat germ system (unlike mammalian cell-free systems) lacks the enzymes which process the GH-precursor (pro-GH or perhaps pre-GH); a similar situation has been demonstrated for several other

polypeptide hormones. The existence of a precursor was also proposed by M. Wallis (University of Sussex) to explain the N-terminal heterogeneity seen in bovine GH.

A major topic of discussion with regard to the biological actions of GH was the role of somatomedins (GH-dependent peptides found in serum). It is not yet clear whether these mediate all the actions of GH, including growth promotion, or whether GH possesses some direct metabolic activity in addition to its role in promoting somatomedin production. Exciting progress in the somatomedin field was described, though it is unfortunate that some work is shrouded in secrecy as a result of the interest of the pharmaceutical industry. At least three somatomedins have now been recognised, distinguished by their relative potencies in different assay systems. Isolation and characterisation of somatomedins A and B was described by L. Frykland and H. Sievertsson (AB KABI, Stockholm). They are moderate-sized peptides, structurally quite different, and neither is a fragment of GH. K. Hall and K. Takano (Karolinska Hospital, Stockholm) described their radio-receptor assays and immunoassays for somatomedins A and B. Levels in normal human serum are quite high (about $2 \mu\text{g ml}^{-1}$ for somatomedin A, $10 \mu\text{g ml}^{-1}$ for somatomedin B). As expected, levels rise in acromegaly and fall in hypopituitary dwarfism. The somatomedins are not completely absent in the latter, however, so these factors are perhaps only partially GH dependent. L. E. Underwood *et al.* (University of North Carolina) described work on somatomedin C (a moderate-sized, basic peptide) and showed that receptors for this occur in most tissues.

Lactogenic hormones can be mentioned only briefly here. R. E. Fellows (Duke University) has characterised ruminant placental lactogens and preliminary structural studies suggest that, as has been predicted, these differ substantially from human placental lactogen.

The idea of holding a conference in which all members of the GH-prolactin family of proteins were considered was an excellent one. Although the growth hormones and lactogenic hormones are clearly related structurally, and must have had a common evolutionary origin, little resemblance has been detected at the biological level. It seems likely that structural resemblances are paralleled by resemblances in biochemical mode of action but these have not yet been clearly established. Perhaps this will be one of the themes of the 4th International Symposium on GH in four years' time. □

review article

Lateral heterogeneity and mantle dynamics

Thomas H. Jordan*

Recent work on the nature of the Earth's lateral heterogeneities yields two conclusions with implications for mantle dynamics: seismic velocity differences between continents and oceans extend to depths exceeding 400 km, and strong lateral velocity gradients at depths greater than 800 km characterise the mantle beneath many subduction zones. These results suggest that more than just the crust and upper mantle are involved in whatever form of convection is responsible for plate motions.

THE study of seismic wave velocities provides the most detailed information about the structure of the Earth's interior and its internal variation of material properties. Until quite recently, it was the consensus among seismologists that below the uppermost mantle the velocity distributions show little geographic variation. With the collection of better data and the application of high-resolution techniques during the past decade, however, it has become clear that this view cannot be maintained. Evidence is rapidly accumulating which indicates the existence of significant lateral heterogeneity throughout the Earth's mantle, even at great depths. Here I attempt to synthesise some of the evidence. Particular attention will be focused on two results which constrain the nature of mantle dynamics.

Continent-ocean heterogeneity

The extreme geographical variations in upper mantle velocities are evidenced by the large-magnitude differences in station anomalies¹ and in regional surface-wave dispersion curves². The available seismic data suggest that the large scale lateral heterogeneity of the upper mantle is largely a consequence of the structural differences between continents and oceans.

Because of the dearth of seismic recording stations in oceanic regions, it is difficult to probe oceanic upper mantle structure using conventional body-wave methods, and most of our information on oceanic structure has come from the study of surface-wave dispersion. Dispersion studies using Love and Rayleigh waves reveal that continental and oceanic surface-wave phase velocities differ out to periods exceeding 300 s (refs 3–6), and from the analysis of these data a reasonably clear picture of the structural differences in the upper 400 km of the mantle has emerged: below a depth of 50 km or so the upper mantle beneath oceans is characterised by a well developed shear-wave low velocity zone (with contrasts as high as 0.5 km s^{-1}), whereas beneath stable continental shields this low velocity zone is weakly

expressed and in some regions it may be nonexistent. Since the shear-wave low velocity zone is associated with a zone of partial melting⁷, the simplest explanation of this difference seems to be a depression of the isotherms beneath the continents, an interpretation that is in accord with modern thermal models.

But this raises a critical question with implications for mantle dynamics: what is the maximum depth to which these continent-ocean differences persist? The popular consensus is that continental plates are on the order of 200 km thick (or less) and that below this depth the sub-continental and sub-oceanic mantles are similar in composition and state^{8,9}. If this model of thin lithospheric plates is correct, then, below a depth of 200 km or so, we should observe very little structural contrast between continents and oceans.

It was first thought that the observed differences in the surface-wave dispersion data required continent-ocean heterogeneity as deep as 500 km, and this evidence was used to argue against the continental drift hypothesis¹⁰. Dziewonski¹¹ has demonstrated, however, that the phase velocity differences may be explained by models with the significant velocity contrasts confined above 200 km depth, which is consistent with the thin-plate concept of having continent-ocean differences concentrated in and above the low-velocity zone.

Although this conclusion is compatible with current concepts, it requires substantial modification^{12,13,18}. Evidence for continent-ocean heterogeneity below the low velocity zone has come from the inversion of free oscillation data and from recent work with shear-wave travel times.

When travel times through the upper mantle beneath the continents are compared with those predicted by the free oscillation models, surprising differences are found: travel times for the average Earth are considerably larger than expected. As shown in Fig. 1, the one-way vertical shear-wave travel times through the upper 700 km of the Earth computed from the free oscillation models (for example UTD124A or B1) are 2–3 s greater than those obtained by the direct measurement of travel times at continental-based seismic recording stations (for example the Jeffreys-Bullen Tables or SLUTD1). Jordan and Anderson¹⁵ have postulated that this baseline difference is due to continent-ocean heterogeneity. Because the eigenperiod data yield estimates of the spherically averaged velocities and because the Earth's surface is two-thirds ocean, this hypothesis requires

*Address: Department of Geological and Geophysical Sciences, Princeton University, Princeton, New Jersey 08540; Present address: Scripps Institution of Oceanography, La Jolla, California 92037.

that the average one-way travel-time difference between continents and oceans be 3–5 s for shear waves. This compares with a difference of only 1–2 s predicted by regionalised Earth models with heterogeneity confined above 400 km (for example models O1 and S1 in Fig. 1, and ref. 17). The implication is that continent–ocean differences extend below this depth.

Fig. 1 Differences in one-way vertical shear-wave travel time from a depth of 700 km to the surface predicted by various velocity models. The JB time (143.6 s, ref. 16) has been subtracted to form residuals. Models UTD124A (ref. 14) and B1 (ref. 15) are gross Earth models which satisfy the free oscillation data; model SLUTD1 (ref. 29) is a shear-wave velocity model derived from continental based travel times; and models S1 and O1 (ref. 11) are regionalised models which satisfy the pure-path surface-wave dispersion data for shields and oceans, respectively.

Direct measurements of vertical travel-time differences for shear waves propagating through the continental and oceanic upper mantles have been made using ScS and multiple ScS phases. These times confirm the existence of a 3–5-s difference inferred from the free oscillation work. Figure 2 summarises the ScS travel-time differences from deep focus events observed by Sipkin and Jordan¹⁸. ScS was used because its travel-time curve is not sensitive to radial variations in velocity and because it seems to be less affected by lower mantle heterogeneity than the direct S phase (see below). In this study the seismic stations were crudely classified into six categories, each representing a particular tectonic setting. The four stations placed into the "normal oceanic" category were Kipapa (Oahu), Afiamalu (Samoa), Raratonga and Bermuda. The ScS times from these stations all show large delays relative to the average "normal continental" times; the average residual is close to +5 s.

There is some doubt as to whether or not the mantle beneath these oceanic island stations is truly "normal". After all, islands are by definition anomalous, and many may be the sites of convective upwelling in the mantle^{19,20}. A further test for the existence of large oceanic delays is provided by the observation of time differences between the arrivals of ScS and ScSScS, an S phase which is twice reflected off the core and once reflected off the surface. ScSScS–ScS time differences are insensitive to the velocity structures in the vicinity of the source and receiver, as well as to any mislocation errors. By using geometries where the surface bounce of ScSScS occurs beneath a deep ocean basin, vertical travel-time differences beneath continents and normal ocean can be obtained. An analysis of 64 ScSScS–ScS time differences has yielded one-way vertical travel-time differences between oceans and continents which average +3 to +4 s (S. A. Sipkin and J.H.J., unpublished). Although somewhat less than the average delay from the island stations, these oceanic delays are compatible with the times inferred from free oscillations.

When combined with the regional surface-wave dispersion data, the large vertical travel-time differences between continents and oceans imply that continent–ocean heterogeneity extends to depths exceeding 400 km^{13,18}. The velocity

Fig. 2 A histogram plot of ScS residuals for each of Sipkin and Jordan's¹⁸ tectonic classification types. The residuals have been formed by subtracting the average normal continental residual for each earthquake studied, a procedure which eliminates errors due to hypocentral mislocation.

differences in the upper 400 km of the mantle are reasonably well constrained by the surface-wave data, and these differences can account for only a second or two of the travel time difference. To satisfy the observed oceanic delay of +3 to +5 s requires the existence of deeper velocity differences.

This inference is supported by the free oscillation results. The models derived from the free oscillation data are typically characterised by lower shear velocities in the depth range 400–700 km than models derived from continental body wave data¹³.

A sketch of possible shear velocity profiles for shield and oceanic upper mantles is given in Fig. 3. These velocities are tentative; it is unclear exactly how the velocity differences are distributed with depth. For example, it is not known if the depths of the major discontinuities are displaced. Analysis of internally reflected waves shows some promise of answering questions such as these²¹, but the precise delineation of oceanic upper mantle structure must await long-line refraction studies using seismometers on the ocean bottom.

The comparisons made here contrast the "typical" structures of the continents and the oceans. Clearly, important variations in mantle structure exist within the confines of the continental margins and the ocean basins. In North America at least, the seismic data suggest that some or even most of these regional variations are associated with the transition from shield to oceanic structure; that is, much of the continent-ocean transition occurs in regions overlain by continental crust. On a transit south or south-west from the Canadian shield there is a general increase in P and S station anomalies¹ and the appearance of a well developed low velocity zone². Across the Rocky Mountain Front this transition is quite abrupt, and the entire western United States may be underlain by mantle that is essentially oceanic in character. It is important to chart the shield-ocean transition across a quiescent continental margin, such as the eastern coast of North America, again, an exercise requiring seismometers on the ocean bottom. Across such a margin

Fig. 3 Possible models of the shear-wave velocity structures beneath continents and oceans. The models are compatible with the surface-wave dispersion data and have a difference in one-way vertical travel time of 3.1 s. —, Shield; ---, ocean.

the lateral velocity gradients may be very large in magnitude.

I have presented elsewhere¹³ a possible model for the upper mantle which can account for the existence of deep-seated continent-ocean velocity contrasts and which is consistent with our knowledge of the upper mantle thermal regime. Briefly stated, this hypothesis postulates that,

Fig. 4 ScS-S residuals at WWSSN stations from a global distribution of deep-focus events²⁰. Black dots are 5° cell means; error bars represent 1 s.e.m. Each symbol corresponds to a different event, and the size of the symbol is proportional to an assigned subjective quality of the reading.

Fig. 5 Correlation plots of S residual versus ScS-S residual (top), and ScS residual versus ScS-S residual (bottom) for times from two Peru-Brazil deep-focus events recorded at United States and Canadian stations²⁸. r_s and r_{scS} are the respective sample correlation coefficients.

beneath the ancient shields, the region which translates coherently in the course of horizontal plate motions (the tectosphere) extends to at least 400 km depth and may occupy the entire upper 700 km of the mantle. Within the continental tectosphere the temperatures are lower, the thermal gradients are super-adiabatic, and the dominant mechanism of heat transport is conduction, not advection. To stabilise the vertical super-adiabatic temperature gradients beneath the shields and the horizontal temperature gradients within the transition from shield to oceanic structure, the model invokes compositional gradients, regions of lower potential temperature consisting of material with intrinsically lower densities.

Admittedly, this model entails a radical departure from the accepted assumption that the thickness of the plates and the lithosphere are identical, it rejects the hypothesis that the continents are decoupled from the mantle at the classical lithosphere-asthenosphere boundary. Furthermore, if the model is correct, continental drift is no longer a simple consequence of plate tectonics. But, in spite of these uncomfortable implications, the model does not seem to be at variance with any significant constraint and thus deserves at least tolerant consideration.

In any case, the seismic data presented here, as well as the old problem of the differences in heat fluxes from the sub-continental and sub-oceanic mantles, require some explanation. The only alternatives I have been able to envisage demand unusual dynamical configurations that seem even more improbable than the tectospheric model.

Lower mantle heterogeneity

Although lateral variability in upper mantle velocities has been known to exist for some time, the existence of lower mantle lateral heterogeneity has been only recently demonstrated. Of course, the difficulty with seeing deep heterogeneity is that it is obscured by geographical variations near the surface, which are generally of larger magnitude in terms of seismic effects. The important work on the subject has been accomplished using a variety of high-resolution techniques, which include body-wave amplitude analysis²², the use of large-aperture seismic arrays²³⁻²⁶, as well as the more conventional measurement of travel times^{27,28}. The most significant result for mantle dynamics to emerge from these studies is the detection of variations in the deep mantle beneath subduction zones.

Data that are particularly suitable for the study of lower mantle structure are the time differences between direct and core reflected phases (PcP-P and ScS-S). At distances greater than 30° or so these differential travel times are not much affected by even gross velocity variations in the crust and uppermost mantle, and they are relatively insensi-

Fig. 6 ScS-S and PcP-P residuals as a function of azimuth from two Peru-Brazil events²⁸. The vertical section through the mantle shows that the large positive residuals in the azimuth window from -15° to -25° define an anomalous zone which lies along the projection of the Benioff zone beneath the Middle America Trench. The section is located on a map view in Fig. 7.

tive to event mislocations as well. Hales and Roberts²⁸ presented 30 observations of ScS-S differential travel times to estimate the radius of the core-mantle boundary. In this study they noticed that the differential travel times showed an unexpectedly large scatter (about 10 s). They speculated that this scatter was due to lateral heterogeneities in the lower mantle, although they did not rule out the possibility of mislocation errors or variations near the source.

I have obtained a considerably larger set of ScS-S times from World-Wide Standard Seismographic Network (WWSSN) recordings of a global distribution of deep-focus events for use in gross Earth modelling^{15,30}. These observations, presented in Fig. 4, show a scatter similar to those obtained by Hales and Roberts. The use of deep-focus events eliminates the near-source traverse through the upper mantle and lends additional support to the hypothesis that the dispersion of times results from velocity heterogeneity in the lower mantle.

A detailed examination of differential travel times, both PcP-P and ScS-S, from two deep focus events in the Peru-Brazil region of South America²⁸ elucidates further the source of the scatter. First, a strong correlation between PcP-P and ScS-S times exists for these events, suggesting the scatter is not simply due to reading errors or some other random noise process. Second, the ScS-S differential times show a strong negative correlation with absolute S times and do not correlate with ScS times (Fig. 5). This implies that the scatter arises from variations along the path of the direct phase, not the core reflection. (This was part of the rationale for using ScS to probe upper mantle heterogeneity, discussed above.) If this interpretation is generally correct for ScS-S, the magnitude of the scatter in these times can be used to estimate the degree of lower mantle heterogeneity. The times in Fig. 4 show a total variation of about 8 s. Supposing the typical scale length for lower mantle heterogeneity to be 1,000 km (an arbitrary number), we obtain velocity contrasts along the path of the S wave of about 5%, a surprisingly high value.

A third result found in the study of the Peru-Brazil data was that the residuals of both PcP-P and ScS-S show a coherent azimuthal dependence (Fig. 6). Of particular note is the grouping of large residuals in the azimuth window -15° to -25° . The rays corresponding to these anomalous times traverse the lower mantle through a region which lies along the extension of the Benioff zone beneath the Middle America Trench, as illustrated in Fig. 6. The existence of an anomaly at approximately this location is supported by two other observations. Davies and Capon³¹ reported anomalous body-wave multipathing at the Large-Aperture Seismic Array (LASA) in Montana for a northern Columbian event, which they suggested might be due to lower mantle heterogeneity. The great-circle ray for this earthquake passes through the anomalous zone defined by the Peru-Brazil data (Fig. 7). In a separate study, Sheppard³² presented an array diagram for the Norwegian Seismic Array (NORSAR), and he noted the existence of a probably source-related anomaly for earthquakes in central America. Events in the Oaxaca district of Mexico separated by as little as 75 km in actual location show array mislocations of as much as 700 km. The magnitude of this splitting must mean that the velocity heterogeneity responsible extends into the lower mantle. Again, the ray paths lie near the anomalous zone delineated by the differential travel-time data (Fig. 7).

Not only do the differential travel times define the location of the anomalous zone, but the positive residuals indicate that the anomaly is characterised by unusually high velocities for both P and S waves. To explain this feature as a thermal anomaly, we found that temperature contrasts of at least 200°C were required, the anomaly being cooler than the surrounding mantle. Thus, the interpretation suggested by these data, and adopted by Jordan

and Lynn is that this high velocity anomaly beneath the Caribbean marks the site of cold material descending in a convecting mantle. The implication of this statement is that the lithospheric slab, or some portion of the slab and its adjacent mantle, penetrates to a depth which exceeds 800 km and which may be greater than 1,400 km.

Evidence is accumulating for deep lateral structure beneath other subduction zones, although the results are less decisive than those for the study described above. Weichert²³ has attributed certain $dT/d\Delta$ and azimuth anomalies for P waves observed at the Yellowknife array to lateral velocity gradients near 800 km depth beneath the Aleutian Arc. Davies and Sheppard²⁴ in their analysis of the LASA array diagram noted that significant changes in the mislocation vectors for some western Pacific regions correlated with transitions from one arc to another, suggesting the anomalies were due to a structure near the source structure. Powell (unpublished), using LASA and two other large arrays in the western United States, has found that this correlation also exists for other regions, notably the Tonga-Fiji Arc. She has used ray-tracing

Fig. 7 Map of the Caribbean area. Shaded region is the surface projection of the mantle below 600 km traversed by rays with large positive residuals from two Peru-Brazil (PB) events²⁷. Also shown are the great-circle path between a northern Columbian (NC) event and LASA, for which Davies and Capon³¹ have observed body-wave multipathing, and the great-circle path between two Mexican events and NORSAR, which show large differences in array mislocation. The arrows are the NORSAR mislocation vectors for these earthquakes³².

techniques to investigate the sources of the anomalies and concludes that lateral velocity variations are present at depths exceeding 800 km. Engdahl³³ has observed travel-time differences at Alaskan stations from deep-focus events in the Tonga-Fiji region which are anomalously large and which require that the plate effects extend deeper than 650 km.

The conclusion that descending lithospheric slabs penetrate deep into the mantle cannot be disputed on

theoretical grounds. A numerical study by Schubert, Yuen and Turcotte³⁴ has demonstrated that temperature contrasts of 700 °C can exist between the slab and the adjacent mantle at 800 km depth, which is consistent with the constraints established in the Caribbean study.

Lateral structure in the mid-mantle beneath subduction zones is perhaps sufficient to explain the scatter in ScS-S times shown in Fig. 4. This hypothesis cannot, however, account for all of the heterogeneity in the lower mantle. Julian and Sengupta²⁷ have found a significant increase in P-wave travel-time residuals at epicentral distances beyond 70° which seems to be associated with lateral structure at depths greater than 2,600 km. These variations show no obvious correlation with surface tectonics.

Actually, the lowermost mantle, which includes Bullen's "region D", has been known to be laterally variable for some time. Phinney and Alexander²² reported geographical variations in the amplitude decay of core-diffracted P waves, a measurement quite sensitive to the velocity structure near the core-mantle boundary.

Array studies³⁴ also indicate the presence of heterogeneity in this region, but the problems with eliminating near-source effects are severe. For example, Kanasewich and others³⁵ saw $dT/d\Delta$ and azimuth anomalies at Canadian arrays and at LASA which they ascribed to a feature near the core-mantle interface beneath Hawaii. (These anomalies were also noted by Davies and Sheppard, ref. 24.) The observation provoked much excitement, since it seemed to confirm a deep mantle source for the Hawaiian hotspot, first suggested by Wilson and Morgan¹⁹. But a recent study by Okal and Kuster³⁶, who looked at the deep mantle beneath Hawaii using the French Polynesian array, failed to support this hypothesis, and Powell (unpublished) has shown that the observations reported by Kanasewich and his colleagues probably result from near-source structure of the sort described above.

Nevertheless, the mantle directly above the core-mantle boundary seems to be quite inhomogeneous, probably on many scales. Julian and Sengupta found lateral correlations in residuals with scales on the order of 1,000 km. Much smaller scale heterogeneity in this region (scale lengths on the order of tens of kilometres) has been postulated by Haddon *et al.*³⁷ to account for the unusual characteristics of certain arrivals precursory to the phase PKIKP.

The relationship of this heterogeneity near the core-mantle interface to mantle dynamics remains obscure.

Implications of lateral heterogeneity

Although the formal study of the Earth's lateral heterogeneity is still in its infancy, two conclusions with profound implications for mantle dynamics seem to be required by the available data. (1) Contrasts in the seismic velocity profiles beneath the stable continental shields and the ocean basins persist to depths exceeding 400 km and may extend as deep as 700 km. (2) Strong lateral velocity gradients exist at depths greater than 800 km beneath many subduction zones. Beneath at least one of these, the Middle American Trench, is a zone of anomalously high seismic velocity which extends to perhaps 1,400 km depth.

I interpret these results in terms of the following hypotheses. (1) Beneath the ancient shields the mass which translates coherently in the course of horizontal plate motions (the tectosphere) is at least 400 km thick. Within this tectosphere, the temperatures are lower, the thermal gradients are super-adiabatic, and the dominant mechanism for heat transport is conduction. Anomalous temperature gradients are dynamically stabilised by compositional gradients¹². (2) The lithospheric slab descending beneath subduction zones (and probably some of its adjacent mantle)

penetrates well into the lower mantle before being thermal equilibrated. These, of course, are only hypotheses formulated from limited data, and they must be vigorously tested before being taken too seriously.

Should either prove to be correct, however, one implication may be drawn which constrains the nature of mantle dynamics: more than just the Earth's crust and upper mantle participates in whatever form of convection is responsible for plate motions. Some sort of deep-mantle convection would be necessary to accommodate the mass flow beneath the continents required by the current geometry of seafloor spreading and destruction, given that the tectosphere is very thick beneath continents. If slabs penetrate the lower mantle, then the implication that deep circulation exists is immediate: we have observed it directly.

Deep-mantle convection is not a radical concept on geophysical grounds, but it does pose a geochemical problem. It has been recognised that the oxidation state (as measured by the ferric-ferrous ratio) and nickel content of rocks seen at the Earth's surface are much larger than would be expected if upper mantle material had even been in equilibrium with the metallic core³⁸⁻⁴⁰. If convective cycling involved material transport at the base of the mantle, in the present epoch or those past, then these observations would be very difficult to explain. On these grounds alone, it may be necessary to postulate the existence of a barrier which prevents the exchange of iron and nickel between the upper mantle and the core. On the basis of the seismic data, however, it is unlikely that this barrier is the entire lower mantle.

As indicated in this report, progress in delineating the Earth's lateral heterogeneities is proceeding rapidly. Much work remains to be done, but it is hoped that the study of lateral variations will provide the keys for unlocking the secrets of mantle dynamics.

X-ray analysis of glucagon and its relationship to receptor binding

Kyoyu Sasaki, Susan Dockerill, Dorota A. Adamiak*, Ian J. Tickle & Tom Blundell†

Biochemistry Laboratory, School of Biological Sciences, Sussex University, Falmer, Brighton BN1 9QG, UK

X-ray analysis of the pancreatic hormone glucagon shows that in crystals the polypeptide adopts a mainly helical conformation, which is stabilised by hydrophobic interactions between molecules related by threefold symmetry. A model is presented in which the glucagon molecule exists in dilute solutions as an equilibrium population of conformers with little retention of structure, and in which the helical conformation is stabilised by hydrophobic interactions either as an oligomer or as a complex with the receptor.

GLUCAGON is a polypeptide hormone of 29 amino acids (ref. 1 and Fig. 1) which is synthesised and stored in the α cells of the islets of Langerhans of the pancreas. The hormone activates glycogenolysis and gluconeogenic pathways resulting in raised blood glucose levels. Rodbell *et al.*² showed that this is mediated by specific binding to a plasma membrane receptor site on the regulatory component of adenylate cyclase of liver and other cells, which gives rise to an increase of intracellular levels of the second messenger cyclic AMP.

An understanding of the nature of the glucagon-receptor interactions depends critically on a proper description of the conformation of the hormone when bound to the receptor. Solution studies show that glucagon exists as an equilibrium population of conformers in dilute aqueous solution^{3,4} but the structure becomes more ordered on self association^{5,6} and in the presence of detergents⁷ or lipid micelles⁸. Preliminary X-ray studies^{9,10} indicated that the crystal structure is mainly helical. We have now carried out a full X-ray analysis at ~ 3.0 Å resolution using the method of isomorphous replacement and anomalous scattering. We describe here our findings on the crystal structure of glucagon; we discuss the relevance of this structure to solution studies, to storage in α cells and to interactions with the receptor; and we compare the structure of this hormone with that of insulin, the only other polypeptide hormone whose structure has been determined by X-ray analysis¹¹.

Glucagon crystals

Glucagon was first crystallised by Staub *et al.*¹² and the space-group ($P2_13$) and unit cell parameters ($a = 47.91$ Å) of the cubic crystals were reported by King⁹. We found that large crystals (> 1 mm diameter) could be grown at pH 9.2 in phosphate buffer by warming a 0.3% solution of glucagon to

50 °C and cooling slowly in a Dewar packed in a hot-box. As pH 9.2 is higher than physiological pH (~ 7.4), we studied the stability of the crystals as a function of pH. Transfer of the crystals to a buffer (acetate or phosphate) in the pH range 5.8–7.5 leads to the cracking of the crystals, but not to their complete disintegration. The crystals still diffract X rays; the maximum resolution (~ 3 Å) of the data is not affected but the mosaic spread is increased. The unit cell dimensions are decreased ($a = 47.1$ Å) and the diffraction pattern shows large intensity changes. Crystals identical to these, but uncracked, can be grown from dilute solutions of glucagon at pH 6.0, but the decreased solubility of glucagon at this pH makes it difficult to grow large crystals. These experiments suggest that the molecular structure is flexible in the crystals as well as in solution.

This made us cautious in our attempts to prepare heavy atom derivatives. W. N. Lipscomb (unpublished) noticed changes in intensities which indicated changes in structure at high pH when heavy atom salts were added. We have shown that metal cations such as Ag^+ and Hg^{2+} and complexes such as PtCl_4^{2-} change the structure at pH 9.2 towards the lower pH crystal form; but many other anionic complexes such as $\text{Au}(\text{CN})_2^-$ and $\text{UO}_2\text{F}_6^{3-}$ cause a change in the reverse direction. Such changes undoubtedly account for the problems encountered by previous workers using the method of isomorphous replacement.

Determination of the structure

We decided to attempt the X-ray analysis of crystals soaked in acetate buffer in the pH range 5.6–7.5. This was for three reasons. First, the pH is closer to physiological pH than at pH 9.2. Second, we found the structure less susceptible to small changes of pH than at pH 9.2. Finally, acetate anions do not form insoluble complexes with metal cations such as Ag^+ , UO_2^{2+} and Sm^{3+} ; on the other hand, these cations have insoluble phosphates and form insoluble hydroxides at pH 9.2.

Soon after our preliminary studies on heavy atom soaking and pH dependence of the crystal structure, W. N. Lipscomb of Harvard University sent us a summary of his X-ray studies in the pH range 9.5–8.5 which we found very helpful. Three heavy atom derivatives using Ag^+ , PtCl_4^{2-} and $\text{Pt}(\text{NO}_2)_4^{2-}$, respectively, were prepared using the conditions shown in Table 1. The three derivatives gave similar but not identical intensity changes in the diffraction patterns. Ag^+ gave a highly isomorphous derivative but the platinum derivatives gave rise to small changes of cell dimensions and the data were attenuated at interplanar spacings of $d < 3.5$ Å.

Three dimensional X-ray data were collected on a Hilger and Watts four-circle diffractometer using a new method for calculation of integrated peak intensities of reflections¹³. For the native and PtCl_4^{2-} glucagon crystals three equivalents

Fig. 1 Sequence of porcine glucagon after Bromer *et al.*¹. Residues 10–25 are written in reverse to show the approximate twofold symmetry of this part of the sequence.

(*hkl*, *lhk* and *klh*) were measured, but for the Ag^+ and $\text{Pt}(\text{NO}_2)_4^{2-}$ glucagon crystals three Friedel equivalents *hkl*, *lhk* and *klh* were also measured to estimate anomalous differences (ΔI). The data were corrected for Lorentz and polarisation effects and absorption corrections were made by the empirical method of North *et al.*¹⁴. Isomorphous difference, anomalous difference and F_{HLE}^2 Patterson functions were computed. F_{HLE}^2 values^{15,16} were given by

$$F_{\text{HLE}}^2 = F_P^2 + F_{\text{PH}}^2 - 2 \left[F_{\text{PH}}^2 F_P^2 - \frac{k^2}{4} (\Delta I)^2 \right]^{\frac{1}{2}}$$

where F_P and F_{PH} are the structure factor amplitudes for the native and derivative crystals and k is the ratio of the real and imaginary parts of the heavy atom scattering factor, and was determined empirically¹⁷. The Harker peaks corresponding to each heavy atom site (Table 1) were identified and the atomic positions were refined using conventional least squares refinement with coefficients $|F_{\text{PH}} - F_P|$ for centric zones, and F_{HLE} for the acentric zones of the Ag^+ and $\text{Pt}(\text{NO}_2)_4^{2-}$ glucagon derivatives. Standard deviations (σ) were estimated for the coefficients and only data greater than 1σ were used. The final residuals are given in Table 1. Difference maps with coefficients $(F_{\text{HLE}} - F_{\text{H}}(\text{calc})) / \alpha_{\text{H}}(\text{calc})$ were used to check for minor heavy atom sites. Refinement using lack of closure procedures was not attempted as the positions of the heavy atoms in the derivatives were strongly correlated.

Phases were first calculated using single isomorphous replacement and anomalous scattering for each of the Ag^+ and $\text{Pt}(\text{NO}_2)_4^{2-}$ derivatives. The correct hand of the heavy atom arrangements was established by calculating difference Fourier for a second derivative using phases calculated for each of the possible enantiomorphic heavy atom arrangements of the first and observing the peak heights at the heavy atom positions of the second. Difference Fourier techniques were also used to relate different heavy atom sets to the same origin.

Phases were calculated using the method of isomorphous replacement incorporating anomalous scattering¹⁸. The figure of merit was 0.84 for the data within the 4.5 Å sphere but decreased steeply especially in the range $3.5 > d > 3.0$ Å where the data were weak and only two derivatives were included. The mean figure of merit was 0.70. The best phases¹⁹ were used to calculate an electron density map, part of which is shown in Fig. 2.

Crystal structure

The electron density map shows well defined helical regions and large volumes of low density which correspond to regions of solvent. Comparison of the electron density with a molecular model using an optical device²⁰ shows that the helical regions correspond to about sixteen residues of α helix, extended at either end by four residues of less regular, right-handed helix. The density of the α -helical region shown in Fig. 3 corresponds well with residues 10–25 of the glucagon molecule. The aromatic sidechains of tyrosine 10, tyrosine 13, phenylalanine 22 and tryptophan 25 are clearly defined although the polar sidechains

$\overline{F_{\text{PH}}}$ and $\overline{F_{\text{H}}}$ are the mean values of the structure factor amplitudes for the derivative structure and the heavy atom constellation, and E_{iso} is the root mean square lack of closure for isomorphous differences for the best phase angle. Z, the occupancy in electrons, and x, y and z the fractional coordinates for each heavy atom position were obtained by least squares F_{HLE} refinement for the Ag^+ and $\text{Pt}(\text{NO}_2)_4^{2-}$ glucagon derivatives, and by refinement against isomorphous differences on the centric zones for the PtCl_4^{2-} derivative. The residuals are defined as

$$R_{\text{C}} = \frac{\sum |F_{\text{PH}} - F_{\text{H}}| - F_{\text{H}}(\text{calc})|}{\sum |F_{\text{PH}} - F_{\text{H}}|}$$

for centric zones and

$$R_{F_{\text{HLE}}} = \frac{\sum |F_{\text{HLE}} - F_{\text{H}}(\text{calc})|}{\sum F_{\text{HLE}}}$$

for all reflections. F_{HLE} is defined in the text.

of arginine and lysine have weaker density. In an α -helical conformation, residues 10–25 have a very approximate twofold symmetry as indicated in Fig. 1 and so the helix fits tolerably, but less well if the direction of the polypeptide is reversed. The correct chain direction was confirmed by the better fit of tryptophan 25, by the well defined electron density of phenylalanine 6 and the continuous density corresponding to residues 1–5 in a non-helical conformation.

Two observations suggest that the polypeptide chain of residues 1–5 is flexible: the density of residues 1–5 is weaker than that of the helix and preliminary studies on the pH 9.2 crystal form indicate changes in the conformation of these residues. Change of pH from 9.2 to around 6 will almost certainly lead to protonation of the amino terminus, and probably formation of an ion pair with the carboxy terminus of the glucagon molecule in the next unit cell. This may be the explanation for the rearrangement indicated in the crystals at pH 9.2. The metal ions Ag^+ , PtCl_4^{2-} and $\text{Pt}(\text{NO}_2)_4^{2-}$ bind between methionine 27 and the N terminus, and their substitution at this position probably induces changes in conformation and crystal packing, similar to those induced by lowering the pH.

The conformations of the non-polar residues in the regions 6–14 and 22–27 are shown in Fig. 3. In the crystal structure they are packed against equivalent residues of other molecules to give hydrophobic regions. The threefold axes of the cubic cell pass close to the glucagon molecule (Fig. 2), and contacts arise between molecules related by these symmetry operations. Figures 4 and 5 show trimeric arrangements of glucagon viewed down the two threefold axes which give rise to extensive intermolecular contacts.

Figure 4 shows the association of the glucagon molecules through contacts between the sidechains of tryptophan 25, leucine 26 and phenylalanine 22 of one molecule and tyrosine 10, tyrosine 13 and phenylalanine 6 of the second. This leads to a triangular structure with the central region around the threefold axis containing solvent and the sidechains of arginines and aspartic acids. In Fig. 5a the association around a second threefold axis leads to contacts between equivalent amino acids at the carboxy terminus of the molecule including phenylalanine 22, valine 23 and leucine 26, which are shown enlarged in Fig. 5b. This hydrophobic region is extended by close packing of sidechains of phenylalanine 6 and tyrosine 10 of other molecules so that the region of non-polar contacts described first is continuous with the second. The result of this complicated cubic close packing is to bury the hydrophobic regions shown in Fig. 3, which are formed when the molecule adopts a helical conformation.

Fig. 2 Part of the $\sim 3 \text{ \AA}$ electron density map viewed along a cell axis. Triangles indicate the positions of the threefold axes in the unit cell.

As King⁹ suggested, the crystal structure approximates to a cubic packing of cylinders; the individual protomers do not have a globular structure which characterises proteins studied by X-ray analysis.

Fig. 3 The conformation of residues (a) 6–14 and (b) 22–29 viewed approximately along the helix axis showing the clustering together of hydrophobic residues.

Fig. 4 A view of a glucagon trimer resulting from heterologous contacts between hydrophobic residues shown in Fig. 3. The region around the threefold axis of symmetry in the centre comprises hydrophilic residues including arginines and aspartates.

Solution structure

In solution at high dilutions glucagon does not have a highly ordered conformation^{2,3}; it is probably flexible, existing as an equilibrium population of conformers. As a result of the low solubility at neutral pH, most solution studies have been carried out at pH 10. At this pH, optical rotatory dispersion⁴ and circular dichroism⁵ indicate that a largely α -helical conformation is induced by concentrating to 3 mg ml⁻¹, and that the conformational change accompanies an association of molecules probably to trimers^{4,5} and possibly to higher oligomers²¹. The association is accompanied by changes in ellipticity and wavelength in the circular dichroism arising from the tyrosine and tryptophan chromophores⁵. These observations can be explained reasonably well in terms of the crystal structure. The association of monomers to trimers resulting in an α -helical conformation probably corresponds to the formation of the trimer shown in Fig. 4, as this arrangement requires a helical conformation, and unlike the trimer shown in Fig. 5, it would give rise to changes in the near ultraviolet circular dichroism due to both tryptophan and tyrosine. It is also consistent with the observation²² that association affects the *pK* of the phenolic hydroxyl of tyrosine 10, which in the crystal trimer appears to be more buried than tyrosine 13.

The far ultraviolet circular dichroism of the glucagon molecules at pH 10 and 3 mg ml⁻¹ is very similar to the spectrum of zinc insulin hexamers which has about 50% of its residues in right-handed helical conformations¹¹. This percentage is less than that observed in the crystal structure of glucagon. The difference, however, may not be real; it may be a consequence of the rather irregular helix in glucagon. Alternatively it may arise partly from differences in conformation between pH 10 and pH 5.8–7.5 where the crystal structure is stable, and partly from a tightening up of the helix as the trimers are associated to higher oligomers as seen in the crystals. Whatever the explanation, the crystal structure demonstrates why a helical arrangement is favoured by association of glucagon molecules; it leads to burying of hydrophobic residues.

Receptor binding

Rodbell *et al.*²³ have found evidence that discrete regions of the glucagon molecule are important to receptor binding and activity. On the basis of studies with des-histidine-glucagon and smaller fragments of the sequence, they suggest that while essentially the entire molecule of glucagon must be considered to be the active species, the histidine at the amino terminus is relatively unimportant to receptor binding.

Fig. 5 A view of a glucagon trimer (*a*) resulting from contacts around the threefold axis involving phenylalanine 22, valine 23 and leucine 26, which are shown enlarged in (*b*).

At physiological concentrations ($\sim 10^{-11}$ M) glucagon must exist as a monomer and so it is unlikely that glucagon trimers or higher oligomers have any role in receptor binding. But the decreased stability with reduced temperature or with the addition of urea indicates that the glucagon receptor complex is stabilised by hydrophobic interactions²⁴. We are

therefore not concerned with conformation of the monomer in aqueous solution, but rather with the structure stabilised by interaction with a hydrophobic surface. A helical structure is stabilised by lysolécithin⁸, cetyltrimethyl ammonium bromide⁷ and glycols²⁷ which increase the hydrophobicity of the environment of the glucagon molecule. The crystal structure shows that

Fig. 6 A schematic representation of the equilibrium between conformers of glucagon. (a) Hypothetical random coil structure in equilibrium with a helical form (b). The helical form is stabilised either as trimers (c) or by association with a receptor (d) by hydrophobic interactions.

a helical conformation is stabilised by association of glucagon molecules to form trimers and higher oligomers. This structure is favoured by hydrophobic contacts because in a helical arrangement non-polar residues are clustered together in two surface regions (Fig. 3). The receptor-bound glucagon may have a similar conformation stabilised by interaction of the glucagon with two hydrophobic regions on the receptor. The importance of both these regions for binding is consistent with the retention of these hydrophobic residues in all active glucagons, the strong receptor binding of des-histidine glucagon, and the inability of either amino-terminal fragments (glucagon 1-21, glucagon 1-23) or carboxy-terminal fragments (glucagon 20-29, glucagon 22-29) to compete with labelled glucagon at its receptor²⁴. The hydrophilic residues adjacent to the two hydrophobic regions may give rise to further stabilising interactions in the glucagon-receptor complex and this may explain the conservation of most of these residues in glucagons from different species. Carbamylation of lysine 12 has little effect on biological activity *in vitro*²⁵; however, modification with a larger group such as trinitrobenzyl²⁶ decreases the biological activity. It also increases the helical content; it probably interacts with the adjacent tyrosine 10 and tyrosine 13, so stabilising the helix but interfering with receptor binding.

This model implies that the glucagon molecule exists in solution as an equilibrium population of conformers with little retention of structure, and that the helical conformation is stabilised by hydrophobic interactions either as an oligomer or as a complex with the receptor, as shown in Fig. 6. This scheme is reminiscent of that of Schwyzer for flexible hormones²⁸. An alternative model would involve an induced fit for the interaction of the glucagon molecule with the receptor²⁹. For instance the C-terminal residues 22-27 containing one hydrophobic area may bind initially in a helical arrangement and induce a helix in the residues 6-21 in a stepwise fashion so that the second hydrophobic area can also bind.

The length of the largely helical glucagon molecule is over 40 Å and the centres of the two hydrophobic regions are about 20 Å apart. This is a very long structure to be bound to one regulatory unit of adenylate cyclase, which may have a molecular weight of about 26,000 (ref. 30) and it is conceivable that glucagon binds two regulatory subunits, each through one hydrophobic region. If these two units are closely homologous and arranged as a dimer with a twofold axis, this would explain the approximate symmetry of the hydrophobic patches around the centre of the helical region shown in Fig. 1. The hydrophobic groups in the centre may form further stabilising interactions with the receptor in the region between the regulatory subunits. A similar twofold symmetry has been proposed for the active conformation of luteinising hormone releasing hormone³⁰, and it has been suggested that this hormone binds two symmetry related subunits in a similar way to the binding of the allosteric effector 2,3-diphosphoglycerate to haemoglobin.

In the crystal structure the region 1-4 does not form a well defined helical arrangement, but changes its conformations easily. This may be facilitated by the presence of glycine 4; glycine can easily attain conformations which are energetically unfavourable to amino acids with sidechains. It is possible that the flexibility also has a role in biological activity. Once the helical region is bound to the receptor the residues 1-4 may change in conformation to interact with the receptor in a way which gives little further thermodynamic stability to the glucagon-receptor complex but which results in the initiation of the biological response. This would be consistent with the antagonistic action of des-histidine-glucagon.

Insulin and glucagon

Our findings on the structure of glucagon contrast strongly with those on the structure of insulin, which is also a polypeptide hormone synthesised in the islets of Langerhans, but which

decreases, rather than increases, glucose levels in the blood. Glucagon is a flexible molecule which easily attains a helical structure in a hydrophobic environment. On the other hand, insulin has a well defined and relatively inflexible globular structure. In the latter case the importance of the three dimensional structure appears to result from the involvement of residues widely separated in the primary sequence in a relatively small receptor binding region¹¹. A stable tertiary structure, however, may have certain disadvantages; it will be degraded more slowly, and, therefore there may be less sophistication in the control of metabolism, as the effect of the hormone might linger on for some time. For insulin the degradation may be facilitated by the presence of a very exposed disulphide at A7-B7. The more flexible structure of glucagon would be more easily degraded by a proteolytic enzyme.

The two hormones, insulin and glucagon, do have similarities. Both associate in concentrated solutions through mainly hydrophobic interactions. The oligomers crystallise *in vitro* and a similar crystallisation seems to be involved in granulation of the hormones in storage. For instance, glucagon granules of certain species are crystalline rhombic dodecahedra (R. Lange and C. Klein, unpublished) and are identical in appearance to the crystals studied by X-ray analysis. Insulin granules are usually crystalline and often have a cubic or rhombohedral close packing of zinc insulin hexamers¹¹. Association of monomers in storage would undoubtedly decrease the rate of enzymatic proteolysis and increase the thermodynamic stability, in addition to providing a concentrated storage form¹¹. In both hormones, the hydrophobic residues which are involved in association also seem to be involved in receptor binding.

We thank Professor W. N. Lipscomb for encouragement and for providing a summary of his experimental results at an early stage in our investigations. We thank Dr J. Schlichtkrull of Novo Research Institute, Copenhagen, for glucagon. We thank Professor S. Shall, Drs M. Rodbell, C. Beddell, P. Goodford, N. Lazarus, W. B. Gratzer and G. H. Beavan, Professor S. Drewes, J. Jenkins, R. Pullen and S. Wood for helpful discussions and encouragement and Professor R. Mason, B. Law, Professor D. C. Phillips and S. Oatley for help with computing and computer drawing of the glucagon molecule. We thank the SRC for financial support.

Tertiary structural differences between microbial serine proteases and pancreatic serine enzymes

Louis T. J. Delbaere, Wendy L. B. Hutcheon, Michael N. G. James† & William E. Thiessen*

Department of Biochemistry, University of Alberta, Edmonton, Alberta T6G 2H7, Canada

Although primary structural homology between bacterial serine proteases and those from the mammalian pancreas is slight, two-thirds of the residues in the bacterial enzyme SGPB as seen at 2.8-Å resolution, adopt a similar polypeptide chain conformation to that of the chymotrypsin family. The three major regions of difference show how this family of proteolytic enzymes has developed from the more primitive bacterial to the relatively sophisticated pancreatic enzymes.

THE primary¹⁻⁸ and tertiary⁹⁻¹¹ structural homologies among the three pancreatic serine proteases have provided an excellent case for the common ancestral origin of these mammalian enzymes. There are also examples of serine proteases, from microbial sources, which have some regions of sequence identical to those of the pancreatic enzymes. The α -lytic protease (ref. 12 and refs. therein) from *Myxobacter* 495 and the two enzymes SGPA (ref. 13) and SGPB (ref. 14) from the extracellular culture filtrate (Pronase) of *Streptomyces griseus* are examples of enzymes with the active site sequences Gly-Asp-Ser-Gly-Gly and His-Cys identical to the corresponding sequences in the mammalian enzymes. These enzymes also have an aspartic acid at a position corresponding to the catalytically important Asp-102 of α -chymotrypsin⁹, elastase¹⁰ and trypsin¹¹. The overall sequence homology between the three enzymes from microbial sources and the pancreatic enzymes is, however, so low (< 20% identity, see Table 1) that tertiary structural homology can validly be questioned.

The question of a common ancestral origin of the bacterial and mammalian enzymes cannot be resolved without a determination of the tertiary structure of one of the microbial proteases. To support an argument for the divergent evolution of the Asp-Ser-Gly proteases, McLachlan and Shotton¹⁵ attempted to predict the tertiary structure of α -lytic protease from a knowledge of the polypeptide backbone conformations of α -chymotrypsin and elastase. Even though large deletions and insertions were required to align the two sequences, these authors were able to fit the amino acid sequence of α -lytic protease into the main-chain backbone of elastase with relatively few contraventions of conventional wisdom concerning globular protein conformation. The results of that study gave promise that the tertiary structures of homologous and functionally similar protein molecules could be predicted from a knowledge of the tertiary structure of one member.

Subtilisin BPN' has an active site geometry very similar to that of the pancreatic serine protease¹⁶. There is, however, no primary or tertiary structural homology of this bacterial enzyme with the mammalian enzymes. Thus for these two

protease classes this particular active site has been achieved through convergent lines of evolution.

To establish the relationship of the bacterial serine proteases with those from the mammalian pancreas we have determined the structure of SGPB at 2.8-Å resolution by X-ray crystallography. Some of the conclusions reached by McLachlan and Shotton¹⁵ are borne out by the present analysis; however, three important regions of the microbial enzymes have no tertiary-structural counterpart in the mammalian pancreatic enzymes.

Experimental procedure

Suitable single crystals of SGPB are obtained from 0.7–1.2 M KH_2PO_4 solutions at pH 4.2. These crystals have the symmetry of space group $P2_12_12$ and unit cell dimensions of $a = 44.16$, $b = 108.91$ and $c = 37.34$ Å. Details of the crystal growth, data collection and processing were reported in a preliminary publication on the 4.5-Å resolution structure of SGPB (ref. 17). In the study reported here Ni-filtered $\text{CuK}\alpha$ radiation from a tube operated at 40 kV and 16 MA was used. This reduction in incident beam intensity from conditions reported earlier¹⁷ increased the lifetime of the crystals by a factor of 3.5 and allowed the measurement of the complete 2.8-Å sphere of data (h kl and Friedel mate h kl , 9,500 reflections) from a single crystal of the native and each isomorphous derivative. The maximum decrease in intensity of the standard reflections was about 12% during the 120 h required to collect these data.

The heavy atom derivatives used in our analysis were prepared by soaking the native enzyme crystals in 1.3 M KH_2PO_4 solutions containing the following heavy atom compounds: 5 mM $\text{Pt}(\text{NH}_3)_2\text{Cl}_2$ for 72 h; 2 mM mersalyl for 48 h; a double derivative from 5 mM $\text{Pt}(\text{NH}_3)_2\text{Cl}_2$ for 12 h first followed by a mixed solution of 5 mM $\text{Pt}(\text{NH}_3)_2\text{Cl}_2$ and 2 mM mersalyl for 24 h; 10 mM K_3IrCl_6 for 72 h and 10 mM K_3IrCl_6 for 24 h. The heavy atom binding sites for these five useful derivatives were identified from cross-phased Fourier maps using the preliminary 4.5-Å phases¹⁷.

A summary of the final heavy atom parameters is included in Table 2. The agreement indices for these five derivatives varied from $R_c = 0.494$ to $R_c = 0.575$, where R_c is the Cullis R factor defined by: $\sum ||F_{PH} - F_P| - |f_H|| / \sum |F_{PH} - F_P|$ summed over the centric data only. The variation of the ratio of heavy atom scattering (f_H) to the lack of closure error (E_H) as a function of $\sin^2\theta/\lambda^2$ and the mean figures of merit for these several ranges are drawn in Fig. 1. All these criteria are well within accepted

limits for a good determination of the protein phases by the multiple isomorphous replacement method.

Sites 4 and 2 (Table 2) for the $\text{Pt}(\text{NH}_3)_2\text{Cl}_2$ derivative were interpreted from a double difference map as a movement of the sulphur side chain of Met-162 on binding the platinum. Site 2 of the 24 h soaked K_3IrCl_6 derivative was interpreted as the loss of one of the bound phosphate groups in the region of the active site Ser-195 (see below). All the heavy atom sites in Table 2 behaved satisfactorily during the least squares refinement cycles.

The electron density map was computed with the native structure factor amplitudes and the best phases¹⁸ derived from the final phasing cycle. Interpretation of this map led to the structure on which the following discussion is based. The phasing program was a locally adapted version of one written by Dr M. G. Rossman; other programs were derived and adapted from the X-ray 70 system compiled by Dr J. Stewart.

Description of structure

To facilitate the comparison of the tertiary structures of the microbial serine proteases with those of the pancreatic enzymes, we have included in Fig. 2 the sequences of SGPB (ref. 14), SGPA (ref. 13), α -lytic protease¹², bovine chymotrypsinogen A (ref. 19) and porcine elastase⁸. The numbering scheme is that of bovine chymotrypsinogen A and chemically similar residues are enclosed in solid lines. The alignment presented here differs in some respects from the alignments previously published¹³⁻¹⁵ and has been based on tertiary structural similarities, a procedure strongly urged by Dickerson²⁰. Figure 2 and Table 2 show that there is considerably more sequence homology among the three microbial serine proteases than between the microbial and pancreatic protease groups.

The amino acid sequence data on SGPB (ref. 14) was invaluable for the interpretation of the 2.8-Å electron density map. The published tentative sequence had to be altered to accommodate two extra residues at positions where the sequence data were incomplete. At residue 65A the sequence Thr-Trp-Ala was altered to Thr-Trp-Trp-Ala to account for an extra lobe of density in the internal hydrophobic core. Chemical and spectrophotometric determinations of Trp in SGPB are also consistent with two tryptophan residues. (L. Jurásek and G. Willick, personal communication). The second region was at residue 186L (Asp-Val-Tyr) which was more consistent with a sequence Asp-Val-Val-Tyr for the interpretation of the

Fig. 1 Variation of the ratio of r.m.s. $|f_H|$ to r.m.s. $|E_H|$ and the figure of merit (\bar{m}) as functions of $\sin^2\theta/\lambda^2$. The r.m.s. $|f_H|$ is the root mean square heavy atom structure factor amplitude, r.m.s. $|E_H|$ is the root mean square lack of closure of the phase triangles. The derivatives are represented by the following symbols: \circ , $\text{Pt}(\text{NH}_3)_2\text{Cl}_2$; \times , mersalyl; Δ , double derivative; \bullet , 3-d soaked K_3IrCl_6 ; \square , 1-d soaked K_3IrCl_6 .

electron density. The extra valine is consistent with the amino acid analyses of peptides derived from this unsequenced region because of the resistance of a valylvaline peptide bond to acid hydrolysis. There are thus 186 amino acid residues in the SGPB molecule.

Several sections of the 2.8-Å resolution electron density map computed over the region of the active site are shown in Fig. 3.

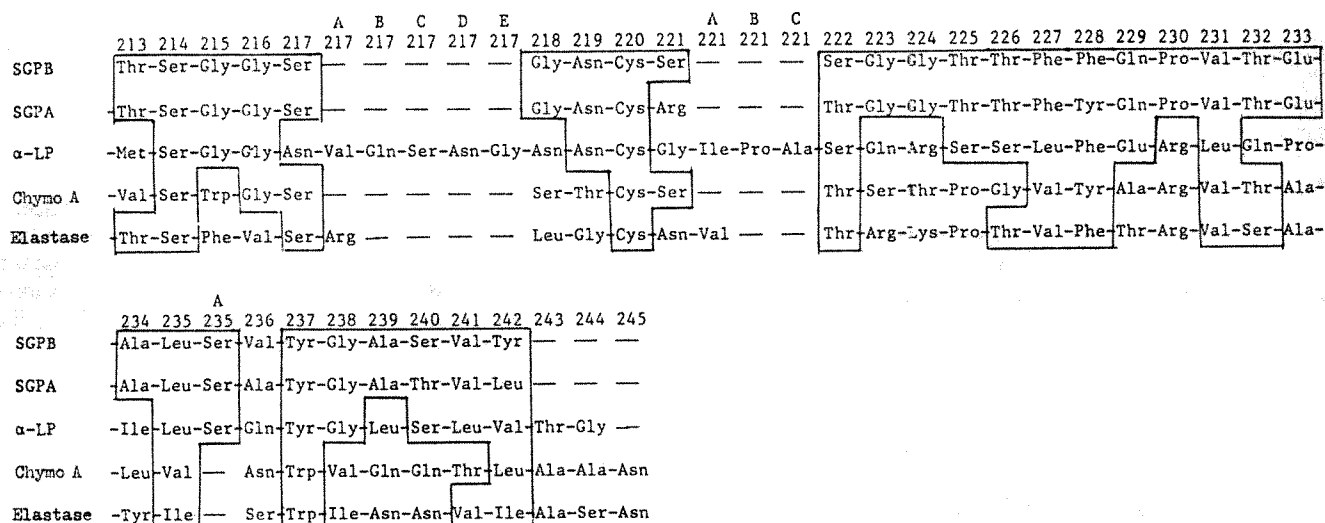

Fig. 2 Comparison of the amino acid sequences of SGPB, SGPA, α -lytic protease, bovine chymotrypsinogen A and porcine elastase. The sequence numbering is that of chymotrypsinogen A (ref. 19). Sequence homologies (chemically similar residues) are denoted by enclosing the amino acid residues within solid lines.

The disposition of the important residues of the catalytic triad is the same as that found for the other pancreatic serine proteases⁹⁻¹¹. Asp-102 is an internal residue and makes a close contact with His-57. The β -hydroxyl group of Ser-195 is also close to His-57, however we feel that the conformation in this region is different in minor respects to that in the active enzyme. The pH optimum is 7.0–8.0 for SGPB and as our study was done at pH 4.2 the enzyme is inactive. There is electron density close to the β -hydroxyl group of Ser-195 which we have tentatively assigned to two phosphate ions that interact with Ser-195 and a segment of the main chain between residues 216 and 217. There is a sulphate binding site observed at low pH in the active site region of one of the molecules of α -chymotrypsin^{21,22} and similar to the present phosphate binding site in SGPB. There is also a sulphate anion bound to the active site in elastase at pH 5.0 and this is replaced by two water molecules as the pH is raised to 8.5 (ref. 23). Serine protease inactivation at low pH may well derive in part from this anion binding in the active site region.

Polypeptide chain conformation

Figure 4 shows in diagrammatic fashion the path of the polypeptide chain. This view corresponds approximately to the standard view of the pancreatic enzymes depicting the molecule from a vantage point over the active site region. The polypeptide chain is folded to produce two hydrophobic cores with the active site located at their junction in a manner similar to that found in the pancreatic proteases. The first core which includes residues His-57 and Asp-102 is made up by folding the first 80 residues (16–128) in an extended conformation producing four major loops. The path taken by the chain in this first section of the molecule is similar to the conformation of the main chain in the mammalian proteases, with some notable exceptions.

The amino-terminal residue Ile-16 is not involved in an internal ion-pair interaction with Asp-194. Figure 4 shows that the amino terminus is on the surface of the enzyme with the *sec*-butyl side chain contributing to the first hydrophobic core and the amino group involved in close contact (possibly ion-pair interaction) with the β -carboxyl group of Asp-126. The chain length from the amino terminus to the 1/2 Cys-42 is much shorter in the microbial enzymes than in the pancreatic enzymes (Fig. 2). McLachlan and Shotton¹⁵ pointed out that

this short chain length was not consistent with the conformation of the polypeptide backbone in this region being identical in the two enzyme families. They did, however, suggest that with a minor conformational change the N-terminal amino group of α -lytic protease could form an ion pair with Asp-194. That this is not the case in the microbial enzymes is indicated by the present model of SGPB and was suggested earlier by the chemical work of Kaplan and Dugas²⁴, who showed that N-acetylation of the α -amino group in α -lytic protease had no effect on its enzymatic activity.

From the 1/2 Cys-42 the main chain traverses the molecule forming the so-called histidine loop before returning to complete the disulphide bridge at 1/2 Cys-58. This segment of the chain has four additional residues, 48A–48D, which are accommodated at the distal end of the histidine loop. Each of the three microbial enzymes SGPA, SGPB and α -lytic protease has these four extra residues.

Figure 2 shows that between residues 65 and 84 a large segment of the main chain of the pancreatic proteases is missing in SGPA and α -lytic protease, whereas only seven residues are deleted in SGPB. This region corresponds to the uranyl loop of α -chymotrypsin²⁵. In SGPA and α -lytic protease this loop is most certainly missing; however, Figure 4 shows that SGPB has a loop that corresponds to the uranyl loop of the pancreatic proteases albeit seven residues shorter.

The aspartate loop, so named because it contains the catalytically important Asp-102, makes up the fourth major loop in the first half of the molecule. The chain in SGPA and SGPB is five amino acids shorter than the chains of the mammalian enzymes and α -lytic protease. The important aromatic side chain (residue 94 which is Phe in the three microbial enzymes) is, however, present and in the SGPB structure serves partially to protect the Asp-102, His-57 interaction from exposure to the solvent. Those residues that are not present in SGPA and SGPB (95–99 inclusive) would form the distal end of the aspartate loop which also serves to shield the His-57, Asp-102 interaction in the mammalian enzymes.

Figure 2 shows that many deletions and insertions are required to produce some semblance of sequence homology between the mammalian enzymes and the microbial proteases in the region 112–191. Olsen *et al.*¹² noted that this region of α -lytic protease shows little homology with the pancreatic enzymes and that the sequence alignment for this section has been rather arbitrary.

Indeed in the microbial enzymes the autolysis loop is missing, but the polypeptide chain follows a path different from that taken in the mammalian proteases (Fig. 4). At residue 125, the only lysine residue of SGPB, the ϵ -NH₃⁺ group makes an ion pair with the α -carboxyl group of the terminal tyrosine-242. It is interesting that both the C terminus and the N terminus of SGPB are involved in ion-pair interactions with the neighbouring residues Lys-125 and Asp-126, respectively. Both SGPA and α -lytic protease have only the basic residue (Arg) at position 125 which may have some influence on the relative stabilities of SGPA and SGPB to denaturing conditions²⁶, although the unusual stability of SGPB to denaturants should be investigated more fully.

Fig. 3 Six sections (1-Å spacing) of the 2.8-Å electron density map of the SGPB molecule in the region of the active site. The residues that make up the active site are labelled. The two disulphide bridges 42-58 and 191-220 are also designated on these sections. The view of the molecule in these sections corresponds approximately to that shown in Fig. 4.

Two other segments of the polypeptide chain in SGPB in the region 123-191 are profoundly different in their locations relative to the tertiary structures of the pancreatic enzymes. The first is that segment of chain that is analogous to the methionine loop in the pancreatic enzymes (residues 168-182). The conformation of the methionine loop in SGPB is such that it occupies a volume in the SGPB molecule that corresponds to the autolysis loop of the pancreatic enzymes. This important structural difference places the side chain of a basic residue, Arg-169, in the appropriate orientation for the internally buried, positively charged guanidinium group to make an internal salt bridge with the carboxylate of Asp-194 (Fig. 4). In view of the methionine loop conformation observed for SGPB it seems unlikely that the microbial enzymes have a zymogen precursor. The enzymes must be catalytically active immediately the folding process has been completed after their synthesis. It could have been predicted from the results of Kaplan and Dugas²⁴ that the positive charge in this crucial ion pair must originate from some other portion of the molecule, but the residue providing the positive charge would have been impossible to predict with confidence. Even though the primary function of this basic residue at position 169 has been lost

through the evolution of the pancreatic serine proteases the basic nature of this residue is conserved in all serine proteases except elastase²⁷.

The other major difference in polypeptide chain conformation occurs at position 186 in the sequence of the microbial enzymes where there are 18 additional residues in SGPA and SGPB, and 17 in α -lytic protease. Clearly these residues do not have a counterpart in the pancreatic proteases. Therefore McLachlan and Shotton postulated that they formed an external loop (termed the compensating extra loop) which would substitute for the residues in the missing autolysis loop. As Fig. 4 shows, residues 186A-186R are not involved with providing a hydrophobic pocket that serves to bury the amino terminus, but rather they are in an extended β loop located on the opposite side of the molecule near the aspartate loop and this extra loop functions as a shield for the Asp-102, His-57 interaction from solvent. The five residues that are missing in the aspartate loop of SGPA and SGPB occur at a point where the loop bends back on itself in an antiparallel β -sheet conformation. These extra residues (95-99) in the pancreatic serine proteases occupy a volume that also shields the Asp-102, His-57 interaction from solvent (namely the hydrophobic residues at position 99). Therefore it appears that the microbial enzymes accomplish this shielding function in a rather extravagant fashion using an extra loop of 17 or 18 amino acid residues to do the task that five residues perform for the pancreatic serine proteases.

From the second disulphide bridge 1/2 Cys-191 to 1/2 Cys-220 the conformation of the polypeptide chain in SGPB

Fig. 4 A diagrammatic representation of the backbone conformation of the polypeptide chain from the 2.8-Å electron density map of SGPB. The labelled regions refer to the residue numbers of Fig. 2. The stippled segments correspond to approximate α -carbon positions for the designated residues. The disulphide bridges 42-58 and 191-220 are indicated.

closely resembles that in the pancreatic family. The residues involved in forming the specificity depression as well as the residues forming the serine loop are in this latter segment of the molecule. To form the serine loop the polypeptide chain traverses the central portion of the molecule and bends back on itself in a manner similar to the histidine loop conformation. From residue 214 to residue 228 there is a large loop of anti-parallel β -pleated sheet structure before the chain emerges from under the extra loop and completes the only two turns of α helix in the whole molecule, residues 231–238. This conformation of the chain is directly homologous to the main chain folding in the pancreatic enzymes. In SGPB, however, the final four amino acids are in an extended conformation and the ultimate residue, Tyr-242, has its aromatic side chain tucked back up into the hydrophobic region between the two central cores.

Active site and primary specificity site

The folding of the polypeptide chain of SGPB produces an active site region between the two hydrophobic cores in the enzyme that qualitatively resembles those active site regions in the pancreatic serine proteases. The amino acid side chains that are involved in the catalytic mechanism, that is, Asp-102, His-57, Ser-195 and Asp-194 are all similarly disposed in these two enzyme families and the catalytic triad is conserved as expected. A second serine residue, Ser-214, occupies a position that places its β -hydroxyl group within hydrogen bond distance of Asp-102 (Fig. 3). The importance of this second serine at position 214 has been pointed out by Kraut *et al.*²⁸ and its functional role in the catalytic mechanism is further substantiated by the study reported here. A much greater degree of homology than shown by McLachlan and Shotton¹⁵ is attained by having a three-residue deletion at position 205 in the α -lytic sequence as indicated in Fig. 2, which correctly places a serine residue at position 214.

The primary binding site of a pipsyl (*p*-iodobenzene sulphonyl) inhibitor on the SGPB molecule was described in the 4.5-Å resolution structural study¹⁷. The present 2.8-Å resolution map shows that this site is made up primarily of two short segments of main chain, residues 192–192B and residues 215–218. There is no evidence for a hydrophobic binding pocket or tosyl hole as seen in the α -chymotrypsin structure^{25,29}, however, in SGPB the binding site is a depression on the enzyme surface. The broad specificity of SGPB³⁰ is consistent with this binding site. The fact that SGPB will also hydrolyse bonds on the carboxyl side of basic residues may be due to the involvement of Glu-192A in this binding. With the second segment of the binding site made up chiefly of glycine residues, the whole binding region involves principally polypeptide backbone and has a shape that would accommodate large hydrophobic side chains¹⁷.

The binding pocket of α -lytic protease deserves comment. The revised alignment presented in Fig. 2 and similar to that proposed by Johnson and Smillie¹³ inserts a pentapeptide 217A–217E in this region. The α -lytic enzyme has a specificity similar to that of elastase and differs from the α -chymotrypsin specificity in that it does not cleave polypeptide chains on the carboxyl side of aromatic side chains. Clearly the extra five residues present in α -lytic protease would alter this region of the specificity depression from that seen in the SGPB structure, thus explaining the different specificities of these two enzymes.

SGPA has a broader but essentially similar specificity to that of SGPB³¹. Cleavage of the insulin B chain by SGPA occurs on the carboxyl side of Leu, Tyr, Phe, Arg and to a lesser degree Glu and Val. This similar specificity to SGPB and the fact that the sequence homologies between SGPA and SGPB are so great in the region of the substrate binding site, indicate that these two enzymes have almost identical tertiary structures in this region.

Evolutionary inferences

Although there are large differences in chain length (186 amino acids in SGPB compared with ~240 for the pancreatic enzymes) and relatively little in the way of sequence homology (Table 1) the overall tertiary structures are similar. Those sections of polypeptide chain which are almost similar, the histidine loop, the aspartate loop, the serine loop and the specificity loop (214–227) provide the probable structural core of the serine proteases. This similarity of structure provides a strong case for the divergent evolution of these serine proteases and demonstrates that this class of enzyme is very ancient and had an ancestor common to the mammals and bacteria.

The tertiary structural differences between these enzymes from such phylogenetically distant organisms also provide information on the evolution of protein structure. The evolution of catalytically inactive zymogens by multicellular organisms is a result of the necessity for the organism to protect itself from auto-digestion. McLachlan³² has suggested a piecemeal growth mechanism for the insertion or deletion of single amino acids into surface loops of an already biologically active protein in such a way that the activity is conserved. This mechanism allows for the addition (or deletion) of surface loops and for the concomitant improvement (or alteration) in biological activity. The structural core is conserved in going from the bacterial to the pancreatic enzymes; however, new stretches of chain have been added (in particular the N terminus and aspartate loop are lengthened, and the autolysis loop added) and other loops have been deleted (the extra compensating loop is lost after the acquisition of additional residues in the aspartate loop) or the function altered or lost (methionine loop).

We thank Drs L. B. Smillie and L. Jurásek for help in the isolation and purification of SGPB and for discussions concerning sequence studies. Ms K. Hayakawa helped with the crystallisation work and the search for heavy atom derivatives. We thank Dr R. J. Fletterick for discussion regarding the phasing program. The photography was done by Ms C. Hicks. This work was supported with the funds from the Medical Research Council of Canada to the MRC group in Protein Structure and Function at the University of Alberta and in part by the US Atomic Energy Commission under contract with Union Carbide Corporation.

Regulation of cell cycle stage-specific transcription of histone genes from chromatin by non-histone chromosomal proteins

Gary Stein, William Park, Cary Thrall, Rusty Mans & Janet Stein

Department of Biochemistry, University of Florida, Gainesville, Florida 32610

RNA transcripts from chromatin of S phase but not G₁ cells contain histone-specific sequences. Chromatin reconstituted with S phase non-histone chromosomal proteins transcribes histone messenger RNA sequences whereas chromatin reconstituted with G₁ non-histone proteins does not. These results suggest that transcription of histone genes is regulated during the cell cycle and that non-histone proteins have a key role in this regulation.

SEVERAL lines of evidence suggest that non-histone chromosomal proteins are important in the regulation of gene expression in general¹⁻⁷, and specifically in the control of transcription during the cell cycle^{8,9}. Variations in the composition and metabolism of non-histone chromosomal proteins throughout the cell cycle are consistent with a regulatory function for these macromolecules¹⁰⁻¹⁷. More direct evidence that non-histone chromosomal proteins are regulatory macromolecules within this context comes from a series of chromatin reconstitution studies which demonstrate that non-histone chromosomal proteins are responsible for the increased transcriptional activity of S phase compared with mitotic chromatin^{8,9}.

In HeLa cells the synthesis of histones is confined to the S phase of the cell cycle¹⁸⁻²¹, and *in vitro* translation data have suggested that the messenger RNAs (mRNAs) for these basic chromosomal polypeptides are associated with a specific class of polysomes only at this time¹⁹⁻²³. We have added adenylic acid residues to the 3'-OH termini of histone mRNAs, and using RNA-dependent DNA polymerase, synthesised a histone complementary DNA (cDNA)²⁴. Using this high resolution probe, we have demonstrated that, consistent with the *in vitro* translation data, histone mRNA is associated with polyribosomes only during the S phase²⁵. In the present studies the histone cDNA was used to demonstrate that transcription *in vitro* of histone mRNA sequences is restricted to the S phase of the cell cycle and that non-histone chromosomal proteins are responsible for regulating the transcription from chromatin of those regions of the genome which contain the information for the synthesis of histones.

Characterisation of histone complementary DNA

To detect the presence of histone-specific RNA sequences, a single-stranded DNA complementary to histone mRNAs was synthesised using RNA-dependent DNA polymerase as described previously²⁴. 7-12S RNA was isolated from the polysomes of S phase HeLa S₃ cells and poly(A)-containing RNAs were removed by oligo(dT)-cellulose chromatography. The remaining 7-12S RNAs directed the synthesis of all five classes of histones in a cell-free protein synthesising system derived from wheat germ. Poly(A) (an average of 35 AMP residues) was added to the 3'-OH termini of the histone mRNAs with an ATP-poly nucleotidyltransferase isolated from maize seedlings. The isolation and properties of this enzyme have been reported²⁶. The polyadenylated mRNAs were then transcribed with RNA-dependent DNA polymerase from

Rous sarcoma virus using dT₁₀ as a primer. The mean sedimentation coefficient of the cDNA in alkaline sucrose was 6.1S which corresponds to a size of approximately 400 nucleotides^{27,28}. The kinetics of hybridisation of the cDNA probe to histone mRNA isolated from polysomes of S phase HeLa S₃ cells were measured to assess the purity of the template RNA and cDNA (Fig. 1). The reaction proceeds with a C_0t_1 of 1.7×10^{-2} (see also double reciprocal plot³⁰ of the data, Fig. 1 inset). Since the molar concentration of the nucleotide sequences in solution determines the rate of hybridisation, comparison of the C_0t_1 of the histone mRNA to that of a kinetic standard such as globin mRNA (complexity of 1,200 bases³¹ and C_0t_1 in similar conditions of 3.8×10^{-3})³² yields a calculated sequence complexity of approximately 5,400 bases which is two times greater than expected for the total complexity of the five histone messages. This is, however, within the range of variation found for the rate of RNA-DNA hybridisation^{30,33-35}. When cDNA and histone mRNA are hybridised in the absence of formamide at 75 °C (data not shown), the C_0t_1 is 5×10^{-3} . From the C_0t_1 of globin mRNA in these

Fig. 1 Kinetics of annealing of histone cDNA to histone messenger RNA isolated from the polysomes of S phase HeLa S₃ cells. 400 c.p.m. of ³H-cDNA (27,000 d.p.m. ng⁻¹) were annealed at 52 °C in sealed glass capillary tubes in a volume of 15 μl containing 50% formamide, 0.5 M NaCl, 25 mM HEPES (pH 7.0) and 1 mM EDTA with either 0.03 or 0.19 μg of histone mRNA in the presence of 3.75 μg of *E. coli* RNA as carrier (●) or with 3.75 μg of *E. coli* RNA in identical conditions (○). The reaction mixtures were assayed for hybrid formation using fraction IV, single-strand specific S₁ nuclease isolated from *Aspergillus oryzae*²⁹. Each sample was incubated for 20 min in 2.0 ml of 30 mM sodium acetate, 0.3 M NaCl, 1 mM ZnSO₄, 5% glycerol (pH 4.6), containing S₁ nuclease at a concentration sufficient to degrade at least 95% of the single-stranded nucleic acids present. The amount of radioactive DNA resistant to digestion was determined by trichloroacetic acid precipitation. No background values have been subtracted. C_0t = mol ribonucleotides s l⁻¹. Inset: Double reciprocal plot of the kinetics of annealing of histone cDNA and histone mRNA. A background of 3% has been subtracted from each point.

conditions ($C_{ot}_1 = 2.0 \times 10^{-3}$)^{36,37} the sequence complexity of histone mRNA is estimated to be 3,000 bases. When the probe is annealed with *Escherichia coli* RNA in either of the above conditions, no significant level of hybrid formation is detected. The low level of S_1 nuclease resistant TCA-precipitable radioactivity may be accounted for by a limited amount (3%) of ^3H -cDNA which is not digested by the enzyme in the incubation conditions used. Thermal denaturation curves of the histone mRNA-cDNA hybrids exhibit a single transition with a T_m of 65 °C in 50% formamide-0.5 M NaCl-25 mM HEPES (pH 7.0)-1 mM EDTA and 95 °C in 0.5 M NaCl-25 mM HEPES (pH 7.0)-1 mM EDTA. These T_m values are consistent with the reported base composition of histone mRNA of 54% G-C (ref. 38).

Additional evidence for specificity of the histone cDNA is its ability to form hybrids with total polysomal RNA isolated from intact S phase HeLa cells ($C_{ot}_1 = 1.8$) and its lack of hybrid formation with G_1 polysomal RNA²⁵. From these findings it is reasonable to conclude that ribosomal (5S, 18S and 28S) and transfer RNA complementary sequences are not present in the histone cDNA. Furthermore, the polysomal RNA isolated from HeLa cells in which histone and DNA synthesis have been blocked by cytosine arabinoside does not form hybrids with the histone cDNA. These results are consistent with data from several laboratories which indicate that histone mRNA is not present on the polyribosomes of HeLa cells treated with inhibitors of DNA synthesis^{19,23,39-42} and additionally rule out the possibility that the cDNA contains detectable amounts of sequences complementary to other S-phase specific, non-polyadenylated RNAs which have been reported to be insensitive to cytosine arabinoside²³.

Transcription of histone-specific sequences from G_1 and S phase chromatin

Evidence has indicated that in HeLa cells histone synthesis is restricted to the S phase of the cell cycle and that the synthesis of these basic chromosomal polypeptides is dependent on concomitant DNA replication¹⁸⁻²⁰. It has also been shown that mRNAs for histones are associated with polysomes during S phase and not during other periods of the cell cycle^{19-21,23,25}. One might therefore anticipate that the synthesis of mRNAs for histones is restricted to the period of DNA replication. Direct evidence for this contention is lacking, however. Therefore, as an initial approach to studying histone gene transcription we examined the abilities of chromatin from G_1 and S phase cells to transcribe histone-specific sequences *in vitro*.

The degree to which *in vitro* RNA transcripts from G_1 and S phase chromatin hybridise to the histone ^3H -cDNA was determined. Figure 2 shows the polyacrylamide gel electrophoretic distribution of RNAs synthesised from HeLa S_3 cell chromatin with *E. coli* RNA polymerase. More than 90% of the RNAs synthesised migrated in the 4-14S region of the gels reflecting the synthesis of RNA molecules which are 75-1,500 nucleotides long. The data in Fig. 3 clearly indicate that although histone-specific sequences are present in the transcripts from S phase chromatin, such sequences are not detected in the transcripts from chromatin of G_1 phase cells. Specifically, the ^3H -cDNA hybridises to S phase chromatin transcripts with a C_{ot}_1 of 2.1×10^{-1} , whereas no hybridisation above the background level of 3% was detected with G_1 transcripts. The extent of hybridisation of transcripts from chromatin of exponentially growing HeLa cells ($C_{ot}_1 = 4 \times 10^{-1}$) was approximately 50% that observed for S phase transcripts (approximately 50% of an exponentially growing population of HeLa cells are undergoing DNA synthesis at any given time) suggesting that thymidine synchronisation used for obtaining S phase cells does not significantly alter transcription of histone mRNA sequences. It should be noted that the T_m (65 °C in 50% formamide-0.5 M NaCl-25 mM HEPES (pH 7.0)-1 mM EDTA and 95 °C in 0.5 M NaCl-25 mM HEPES (pH 7.0)-1 mM EDTA) of the hybrids formed between the ^3H -cDNA and S phase chromatin

Fig. 2 Polyacrylamide gel electrophoresis of RNAs transcribed from HeLa S_3 cell chromatin in the presence of ^{14}C -ATP ($0.4 \mu\text{Ci ml}^{-1}$). Electrophoresis was carried out according to the method of Schochetman and Perry⁴³ in the presence of 4S, 18S and 28S RNAs as internal markers. RNA was transcribed using Fraction V *E. coli* RNA polymerase prepared according to the method of Berg *et al.*⁴⁴ Transcription was carried out for 70 min at 37 °C in a Dounce homogeniser fitted with a wide clearance pestle, and the reaction mixture was periodically homogenised to maintain chromatin solubility. The incubation mixture in a final volume of 10 ml contained: 0.04 M Tris (pH 8.0); 4 mM MgCl_2 ; 1 mM MnCl_2 ; 0.02 mM EDTA; 0.008% β -mercaptoethanol; 0.4 mM each of ATP, CTP, UTP, and GTP, $150 \mu\text{g ml}^{-1}$ of DNA as chromatin, and 600 U RNA polymerase. RNA was extracted as follows. The reaction was brought to a concentration of 1% SDS-0.1 M NaCl-0.01 M sodium acetate-1 mM EDTA (pH 5.4) and incubated at 37 °C for 15 min. Following two extractions with equal volumes of phenol and chloroform-isoamyl alcohol (24:1, v/v) and two extractions with chloroform-isoamyl alcohol, nucleic acids were precipitated with 3 volumes of ethanol. The pellet was resuspended in 10 mM Tris-0.1 M NaCl-5 mM MgCl_2 (pH 7.4) containing $40 \mu\text{g ml}^{-1}$ of DNase I and incubated at 37 °C for 60 min. Following one extraction with phenol-chloroform-isoamyl alcohol and two with chloroform-isoamyl alcohol, the aqueous phase containing the RNA transcripts was chromatographed on Sephadex G-50 fine and eluted with 50 mM Tris-0.1 M NaCl-1 mM EDTA (pH 7.2). RNA was precipitated with 3 volumes of ethanol. For hybridisation analysis the RNA was resuspended in 25 mM HEPES-0.5 M NaCl-1 mM EDTA, pH 7.0.

transcripts is identical to the T_m of the ^3H -cDNA-histone mRNA hybrids. From a comparison of the C_{ot}_1 values of the S phase chromatin transcript-cDNA and histone mRNA-cDNA hybridisation reactions it can be estimated that 8% of the S phase transcripts are histone-specific sequences. The figure of 8% is based on the assumption that the histone mRNA preparation consists entirely of histone mRNA sequences. The presence of other sequences in the preparation would require a corresponding reduction in this figure.

To rule out the possibility that endogenous RNAs associated with S phase chromatin at least in part account for the formation of hybrids with histone cDNA, the following approach was pursued. S phase chromatin was placed in the transcription mixture without RNA polymerase and an amount of *E. coli*

Fig. 3 Kinetics of annealing of histone cDNA to *in vitro* transcripts of chromatin from G_1 and S phase HeLa S_3 cells. 400 c.p.m. of ^3H -cDNA (27,000 d.p.m. ng^{-1}) were annealed at 52°C to either 0.15 or 1.5 μg of RNA transcripts from G_1 (\blacktriangle) or S phase (\bullet) chromatin. 400 c.p.m. of cDNA were also annealed to 1.5 μg of *E. coli* RNA isolated in the presence of S phase chromatin (\star). *E. coli* RNA was included in each reaction mixture so that the final amount of RNA was 3.75 μg . Exponentially growing HeLa S_3 cells were maintained in suspension culture in Joklik-modified Eagle's MEM supplemented with 3.5% each of calf and foetal calf serum. Cells were synchronised as described previously¹⁰. S phase cells were obtained by synchronisation with 2 cycles of 2 mM thymidine block. 3 h after release from the second thymidine block cells were collected, at this time 98% of the cells were in S phase as determined by autoradiographic assessment of ^3H -thymidine labelled nuclei. G_1 cells were obtained 3 h after selective detachment of mitotic cells from semiconfluent monolayers. 97% of the cells were in the G_1 phase of the cell cycle; incorporation of ^3H -thymidine into nuclei could not be detected autoradiographically, reflecting the complete absence of S phase cells. Nuclei were obtained by washing cells 4 times in 80 volumes of Earle's balanced salt solution and lysing the cells in 80 volumes of 80 mM NaCl–20 mM EDTA–1% Triton X-100 (pH 7.2). The nuclei were washed three times with the lysing medium and then twice with 0.15 M NaCl–0.01 M Tris (pH 8.0). Nuclei isolated in this manner are free of cytoplasmic material when examined by phase contrast and electron microscopy. Lysis of nuclei was achieved by suspending the nuclear pellet in triple glass-distilled water with several strokes of a wide-clearance Dounce homogeniser. The chromatin was allowed to swell at 4°C for 30 min, pelleted at 20,000g for 15 min, resuspended in distilled water, and again pelleted at 20,000g.

RNA equivalent to the amount of RNA transcribed from S phase chromatin was added. RNA was immediately extracted by the same procedure used for the isolation of *in vitro* transcripts. When this control RNA was annealed with the cDNA no significant level of hybridisation was observed (Fig. 3). Additionally, RNA isolated from S phase chromatin in the absence of carrier shows no hybrid formation with the cDNA. These results establish that endogenous, histone-specific sequences associated with S phase chromatin are not contributing significantly to the hybridisation observed with S phase *in vitro* transcripts. The findings presented so far are consistent with the argument that the genetic sequences which code for the synthesis of histones are available for transcription from chromatin during the S phase of the cell cycle but not during G_1 .

Regulation of histone-specific sequences by non-histone chromosomal proteins

Although evidence has been presented which strongly suggests that among the non-histone chromosomal proteins are macromolecules which are responsible for the regulation of tran-

scription during the cell cycle, the evidence is of a correlative nature. To examine directly the involvement of non-histone chromosomal proteins in the control of cell cycle stage-specific gene readout, we pursued the following approach. Chromatin isolated from G_1 and S phase cells was first dissociated, in 3 M NaCl–5 urea–0.01 M Tris (pH 8.3), and the DNA was pelleted at 150,000g for 36 h. Proteins were fractionated into histone and non-histone chromosomal protein fractions by the QAE–Sephadex method of Gilmour and Paul⁴⁵. Chromatin was reconstituted by the gradient dialysis procedure of Bekhor *et al.*⁴⁶. The details of these methods⁸ and evidence for fidelity of chromatin reconstitution^{46–48} have been reported. DNA was prepared by the method of Marmur⁴⁹, treated with pancreatic ribonuclease A (50 $\mu\text{g ml}^{-1}$ for 30 min at 37°C) and Pronase (50 $\mu\text{g ml}^{-1}$ for 2 h at 37°C), and then extracted twice with phenol and chloroform–isoamyl alcohol before use.

In vitro RNA transcripts from chromatin reconstituted with G_1 non-histone chromosomal proteins and from chromatin reconstituted with S phase non-histone chromosomal proteins were annealed with histone ^3H -cDNA. Figure 4 shows that RNA transcripts from chromatin reconstituted with S phase non-histone chromosomal proteins hybridise with histone cDNA although those from chromatin reconstituted with G_1 non-histone chromosomal proteins do not exhibit a significant degree of hybrid formation. It should be emphasised that the kinetics and extent of hybridisation with the cDNA are the same for transcripts of native S phase chromatin and transcripts of chromatin reconstituted with S phase non-histone chromosomal proteins (Fig. 4). Furthermore, the amounts of RNA transcribed and the recoveries during isolation of these transcripts from the native and reconstituted chromatin preparations are essentially identical. These results imply a functional role for non-histone chromosomal proteins in regulating the availability of histone sequences for transcription from chromatin and, taken together with the polysomal data presented previously²⁸, suggest that, in intact cells, regulation of histone gene expression during the cell cycle may reside, at least in part, at the transcriptional level. Such a regulatory role for non-histone chromosomal proteins is in agreement with results from several laboratories which have indicated that these

Fig. 4 Kinetics of annealing of histone cDNA to *in vitro* transcripts from native and reconstituted chromatin. 400 c.p.m. of ^3H -cDNA were annealed at 52°C with either 0.15 μg or 1.5 μg of RNA transcripts from chromatin reconstituted with S phase non-histone chromosomal proteins and DNA and histones pooled from G_1 and S phase cells (\circ), chromatin reconstituted with G_1 non-histone chromosomal proteins and DNA and histones pooled from G_1 and S phase cells (\triangle), native S phase chromatin (\bullet) and native G_1 chromatin (\blacktriangle). *E. coli* RNA was included in each reaction mixture so that the final amount of RNA was 3.75 μg .

proteins are responsible for the tissue-specific transcription of globin genes^{2,36,50}.

Although it seems that among the non-histone chromosomal proteins are macromolecules which regulate the transient readout of histone genes during the cell cycle, the regulatory elements involved have yet to be defined. It is not clear whether the non-histone chromosomal proteins which render histone sequences transcribable during S phase, are synthesised at the onset of DNA replication or whether they are pre-existing proteins which are enzymatically modified at this time. Post-translational modifications of non-histone chromosomal proteins, particularly phosphorylation, have been implicated as having a key role in dictating structural as well as transcriptional properties of the genome. Furthermore, it remains to be established whether control is of a positive or negative nature. Since the genetic sequences for histone mRNAs in HeLa cells are reiterated⁴², the possibility arises that a single cell may contain multiple copies of the proteins which control the expression of histone genes. This system may therefore be readily amenable to the isolation of such regulatory proteins.

We thank Dr Francis Davis for discussions and Jeudi Davis for assistance with cell culture. These studies were supported by grants from the NSF, from the NIH, from the American Cancer Society and from the Atomic Energy Commission.

Theory and practice for studies of peptides by ¹⁵N nuclear magnetic resonance at natural abundance: gramicidin S

G. E. Hawkes & E. W. Randall

Department of Chemistry, Queen Mary College, Mile End Road, London E1 4NS, UK

C. H. Bradley

Bruker-Physik AG, 7501 Karlsruhe-Forchheim, West Germany

The low-abundance isotope of nitrogen, ¹⁵N, is now accessible to study by the latest high resolution nuclear magnetic resonance techniques. Structure and motion in polypeptides of moderate size may now be usefully investigated in this way.

THE difficulties in observing magnetic resonance spectra (NMR) of the ¹⁵N nucleus at the natural abundance level (0.36%) are well established¹⁻³. Recent advances in technique⁴⁻⁶, however, specifically the pulse-Fourier transform method with ¹H noise decoupling, have made it possible to obtain useful spectra. The initial studies on natural abundance ¹⁵N NMR, however, used neat liquid samples^{4,7} or highly concentrated solutions of low molecular weight material^{3,5}. Of course the low sensitivity has occasionally been elevated for ¹⁵N (as for other nuclei, such as ¹³C) by isotopic enrichment⁸. Labelling techniques then can add a new dimension to mechanistic studies, as witnessed by the nitrosation work on peptide

models, in which the fate of ¹⁵N-labelled nitrite ion is followed by NMR⁹.

The rewards of studying ¹⁵N NMR are first, that one observes a high resolution nucleus that may participate directly in fundamental chemical and biological processes (for example, acid-base equilibria, tautomerism, hydrogen bonding and coordination), and second, that the spectra of complex nitrogen-containing molecules, for example peptides, should be far simpler, and therefore easier to interpret than their ¹³C- or ¹H-spectra which can be over-rich in resonances.

Some general considerations for ¹⁵N NMR

The sensitivity of ¹⁵N in an NMR experiment at constant field compared with ¹³C (both isotopes at natural abundance) is about 1:30. Thus, to obtain comparable signal-to-noise ratios from experiments using signal averaging on the two species at similar total nitrogen and carbon concentrations would take about 900 times longer for ¹⁵N than for ¹³C, which is already a difficult nucleus. A combination of larger sample volumes (25 mm outer diameter tubes) and a spectrometer

with a higher operating magnetic field (4.2 T) may be used to bring lower sensitivities within range for either ^{13}C or ^{15}N provided the samples are not limited in amount. Sensitivity gains of between 15 and 20 which have been achieved for ^{15}N in this way are reported here. Sample concentrations may now be reduced and material of higher molecular weight may be studied. Additionally various new experiments have become accessible, which can give useful information about motional as well as structural characteristics. (A very elementary exposition of the basic NMR experiment is given in ref. 10.)

Lippmaa *et al.*¹¹ have found long (50–500-s) spin-lattice relaxation times (T_1) for ^{15}N in a range of small organic molecules. Where spectra are to be accumulated by repetitive pulse-Fourier transform methods, saturation of the resonances is then very easy, and can result in reduced signal intensity. This problem may be overcome by the addition of paramagnetic material to the sample⁶ to shorten T_1 , or by the use of long delays ($> T_1$) between pulses. We have now found that for larger molecules the problem of long T_1 s is not so serious (see below). (A useful introduction to relaxation times is ref. 12.)

The nuclear Overhauser effect (NOE) (reviewed in refs 12–14) is a well known intensity effect that occurs in double resonance experiments¹⁰. For ^{15}N , as for other nuclei, it can be defined as the ratio of the proton-decoupled ^{15}N signal intensity (I_D) to the proton-coupled intensity (I_0). If the motion of the molecules is fast enough (small correlation time, τ_c) then in the absence of exchange effects on T_1 , the NOE (denoted by $1 + \eta$) is given by

$$\frac{I_D}{I_0} = 1 + \eta = 1 + \frac{\gamma(^1\text{H})T_{1D}^{-1}}{2\gamma(^{15}\text{N})T_1^{-1}} \quad (1)$$

where T_{1D} is the ^{15}N - ^1H dipole-dipole contribution to the total ^{15}N relaxation time, T_1 . Since the signs of the magnetogyric ratios (γ) of ^{15}N and ^1H are opposite ($1 + \eta$) can be negative^{4,7}. The maximum possible NOE, which occurs for the 100% dipole-dipole case, is in fact -3.9. An inverted absorption mode signal then results. Other mechanisms for relaxation

for example, spin-rotation, chemical shift anisotropy^{11,13,14} may, however, compete with the dipole-dipole (that is, $T_{1D} > T_1$) thus reducing the NOE. In unfavourable situations $1 + \eta \rightarrow 0$, and zero ^{15}N signal results⁷. Again, addition of paramagnetic material to the sample may be used, this time to provide a dominant electron-nucleus (^{15}N) relaxation mechanism⁶. Then $T_1 \ll T_{1D}$ giving $1 + \eta \rightarrow 1$. An alternative way of suppressing the NOE which has been used frequently for ^{13}C is the gated decoupling technique¹⁵. We report here its first use for proton-decoupled ^{15}N systems to give ^{15}N resonances decoupled but without NOE.

The strength of the dipole-dipole mechanism depends on the inverse sixth power of the ^{15}N - ^1H internuclear separation and so it is most efficient for ^{15}N with directly bonded protons. To obtain inverted absorption mode ^{15}N signals (that is a significant NOE), however, it is not necessary that the protons be directly bonded, as has been shown by Lichter and Roberts⁷ on nicotine and Katz *et al.*⁸ on pheophytin a. What is necessary is merely that other relaxation mechanisms for ^{15}N should not be significant relative to the dipole-dipole.

If the approximation of fast motion does not hold, however, reduced NOEs can still result even if the dipole-dipole mechanism dominates. Allerhand and Oldfield¹⁶ have shown this for ^{13}C - $\{^1\text{H}\}$ experiments. (I - $\{S\}$ signifies observation of the I spins with saturation of the S spin transitions.) We report a similar analysis for the ^{15}N - $\{^1\text{H}\}$ system (Fig. 1a). Figure 1b shows a plot of T_1 and T_2 for a single ^{15}N - ^1H interaction, with a magnetic field of 2.1 T and internuclear distance, $r = 1.03$ Å. The expected reduction in the NOE occurs also for ^{15}N , and most importantly the sign of the signal changes as τ_c changes. In the region of fast motion (characterised by the inequality, $\omega^2\tau_c^2 \ll 1$, where ω is the resonance frequency) the fully inverted signal is obtained. When, however, $\omega^2\tau_c^2 \gg 1$, the signal is no longer inverted and the NOE reaches a limiting value of +0.88. At intermediate values of τ_c (about 6×10^{-9} s) signal

Fig. 1 a, Theoretical maximum ^{15}N - $\{^1\text{H}\}$ NOE. ^{15}N at 9.12 MHz; b, ^{15}N - ^1H dipole-dipole relaxation time. ^{15}N at 9.12 MHz.

nulling occurs. This motional nulling is to be contrasted with the original nulling condition we mentioned: the competitive relaxation situation.

We have observed a third nulling situation when off-resonance single frequency decoupling¹⁰ is used. Such experiments have proved to be very useful in overcoming assignment difficulties, notably in ¹³C NMR¹⁷. This possibility, and even a fourth nulling condition resulting from the gated decoupling experiment, have recently been discussed briefly¹⁸.

§ *trans* isomer in MeOH-d₄.

¶ *cis* isomer in MeOH-d₄.

Nitrogen is an atom which often participates directly in chemical exchange phenomena. The ¹⁵N spectrum of a nucleus exchanging between two or more chemically shifted sites may display resonances due to each particular environment (slow exchange), a single averaged resonance (fast exchange), or at intermediate exchange rates much broadened resonances which are difficult to observe. Even if the sites are equivalent, exchange may affect the spectrum by causing decoupling of ¹⁵N from an attached labile proton. Assignment can then not be made by observation of multiplicities.

Contrary to first assessments¹⁹, it should not be thought that the NOE of a nitrogen attached to a labile proton need necessarily be affected by the exchange, simply because the multiplicity is lost. In other words, the single upright resonances in single resonance spectra may be inverted by double irradiation of the sample. We have observed this behaviour for the amino resonances of viomycin sulphate, for which the amido portions exhibited normal multiplicities (unpublished results of L. F. Farnell, G.E.H. and E.W.R.). The original expectation of an exchange effect on the NOE came from the possibility that modulation of the scalar ¹⁵N-H interaction (which gives rise to the multiplicity) could affect *T*₁ and thus the NOE. A dominant mechanism of this sort could give a value 1+η = +10.86. Leipert and Noggle have shown, however, that even when the scalar relaxation is at a maximum it is most unlikely to dominate²⁰.

On the other hand, it is conceivable that exchange could affect the NOE by a new consideration. Suppose we have fast exchange of ¹⁵N between inequivalent sites, one can then obtain

the average NOE. Nulling could then occur if in the slow exchange limit the signals are opposite in sign.

Applications to peptides

As a necessary preliminary to studying larger peptides we have investigated the types of structural information which may be obtained by ¹⁵N NMR work at natural abundance on small model systems; moreover systems wherein complicating effects of chemical exchange at nitrogen are minimal. Tables 1 and 2 show the ¹⁵N chemical shift data for some amino acid methyl ester hydrochlorides (some of which have been the subject of a preliminary communication⁹) and some N-acyl amino acids. The chemical shift variations which we have so far observed are due almost entirely to structural changes because medium effects have been shown to be small. For example a pH study on glycine methyl ester hydrochloride showed the ¹⁵N shift was insensitive to pH change in the range 0-4. Similarly the N-formyl derivatives (Table 2) showed a negligible shift with concentration in the range 1-4 M in DMSO, and for the N-acetyl derivatives the effect of changing the solvent from DMSO to methanol is to impart only a small (1.3±0.5 p.p.m.) downfield shift. The cause of this last small effect is probably the differing intermolecular hydrogen bonding situations in the two solvents.

For each example shown in Table 2, a single ¹⁵N resonance was generally observed and is due²³ to the *trans* amide form.

Resolution of the *cis* and *trans* resonances of N-acetyl L-proline in DMSO (about 71% *trans* in DMSO solution²⁴) was achieved only at the higher resonance frequency (18.24 MHz, 4.2 T) and not at 9.12 MHz (2.1 T). The shift difference was 0.3 p.p.m. with the *cis* signal being to higher field. This illustrates the second advantage, further to the sensitivity gain, of operating at higher frequency. For a solution in methanol-d₄ the solvent induced shift was sufficient to give resolved signals at 9.12 MHz: the signal for the *cis* isomer was 0.6 p.p.m. to low field.

The differential effects, amounting to about 3.5 p.p.m. (±0.3 p.p.m.), on ¹⁵N chemical shifts in amino acids by formylation and acetylation (Table 2) lead in theory to the possibility of obtaining sequence information for small peptides by ¹⁵N NMR. Table 3 shows the ¹⁵N chemical shifts of some dipeptide and a tripeptide N-acetyl derivatives, which were obtained to test this possibility. Consider first the series: AcGly, AcGly¹Gly², AcGlyAla, AcGlyLeu. The signal at about 89 p.p.m. for all must be due to Gly (Gly¹ for AcGly¹Gly²), and demonstrates that the introduction of the C-terminal amino acid unit has a negligible effect on the ¹⁵N shift. This is verified by the comparisons AcAla, AcAlaGly (Ala at about 104.5

Table 3 ^{15}N chemical shifts of some N-acetyl peptides

‡ Numbers in parentheses are relative signal intensities.

p.p.m.) and AcLeu, AcLeuGly (Leu at about 102 p.p.m.).

The introduction of an N-terminal amino acid unit does, however, shift the ^{15}N resonance of the C-terminal unit (in the dipeptides) away from the acetyl amino acid position as shown by the comparisons:

AcGly	AcGlyGly	AcAlaGly	AcLeuGly
89.4	84.0	83.5	84.6 p.p.m.

The shift seems to be insensitive, however, to the structure of the N-terminal amino acid unit. This is reasonable, since a change in the N-terminal unit is a γ or δ effect across a carbonyl group:

Thus the ^{15}N chemical shift of glycine, for example, in a peptide chain would be expected to be about 84 p.p.m. ± 0.5 p.p.m. at least in DMSO solution. This is verified by the shifts for N-acetyltriglycine:

Ac-Gly-Gly-Gly
89.7 84.0 84.0 p.p.m.

In the same way that glycine in a peptide gives a ^{15}N shift about 5.4 ± 0.5 p.p.m. upfield from N-acetyl glycine, so also the alanine in AcGlyAla gives a shift 5.6 p.p.m. upfield from the value for AcAla, and leucine in AcGlyLeu is 5.3 p.p.m. upfield from AcLeu. Thus, the theoretical promise of getting sequence information is in practice not realised for these derivatives in DMSO solution. The relative numbers and the nature of the peptide components are, however, easily obtained.

^{15}N study of gramicidin S

The naturally occurring, antibiotic, cyclic decapeptide gramicidin S, molecular weight 1,120, has the primary structure cyclo-(-D-Phe-L-Pro-L-Val-L-Orn-L-Leu) $_2$ and has been studied extensively as a model for proteins by both proton²⁵ and ^{13}C NMR²⁶⁻²⁸. Its relatively high solubility in both methanol and DMSO makes it a suitable substrate for testing the applicability of ^{15}N NMR at the natural abundance level to higher molecular weight material. Spectra obtained at 2.1 T are shown in Fig. 2

(the chemical shifts are summarised in Table 4) and illustrate the excellent resolution obtainable in spite of the relatively long accumulation times required. The backbone amide nitrogens resonate in the region 93–116 p.p.m. whereas the side-chain $-\text{NH}_2$ of ornithine is substantially to higher field. That a spectrum in DMSO solution (Fig. 2c) showed no amide nitrogen resonances is noteworthy. It is the first example of nulling of ^{15}N resonances by the restricted motional effects outlined above.

To confirm this proposal, ^{13}C NMR spectra of gramicidin S at 22.6 MHz were recorded, in various solvent and concentration conditions with ^1H decoupling, and the half-widths of various well resolved resonances were measured (Table 5). The full resonance width at half height ($\Delta\nu_i$ Hz) is related to the spin-spin relaxation rate, T_2 , by $1/T_2 = \pi\Delta\nu_i$ (s^{-1}). From these data, effective correlation times (τ_c) for overall reorientation of gramicidin S were calculated (Table 5). The correlation times obtained for solutions 0.2 M in methanol and 0.3 M in

Fig. 2 ^1H Noise decoupled natural abundance ^{15}N NMR spectra (9.12 MHz) of gramicidin S. Average accumulation time per spectrum was about 36 h. These are magnitude spectra and thus contain no information on the sign or magnitude of the NOE. X marks the position of coherent noise from the deuterium lock.

DMSO were $(6 \pm 3) \times 10^{-10}$ s and $(5.4 \pm 0.8) \times 10^{-9}$ s, respectively. (The first value agrees with that obtained by Allerhand and Komoroski²⁷ from ^{13}C T_1 measurements on a more dilute solution of gramicidin S in methanol: $\tau_c = (3.3 \pm 0.2) \times 10^{-10}$ s.) Use of these data in Fig. 1 shows that the ^{15}N resonances from the 0.2 M solution in methanol must have a near maximum NOE ($1 + \eta = -3.9$ to -3.6), whereas those from the 0.3 M solution in DMSO are in the nulled region.

Further confirmation that the ^{15}N resonances from the solution of gramicidin in DMSO were nulled by the NOE was provided by two experiments at 18.2 MHz: a variable temperature experiment and a gated decoupling experiment. The ^1H decoupled spectrum of gramicidin (0.15 M in DMSO) at about 18 °C showed no amide resonances and a strong NH_2 reso-

Table 5 Average ^1H decoupled ^{13}C resonance half widths for gramicidin S

Full line widths at half height (± 1.2 Hz) are estimated to include about 1 Hz instrumental broadening. NR, not fully resolved—overlapping resonances.

nance (Fig. 3b). An increase of sample temperature from 18 °C to 47 °C decreased the correlation time sufficiently to quench the nulling and give amido resonances showing a partial NOE, as can be seen in Fig. 3. In the gated decoupling experiment the conditions were chosen to yield decoupled resonances without NOE and the spectrum in Fig. 3b was thereby made to yield amido resonances opposite in phase to those obtained at 47 °C. These experiments were feasible only because of the increased sensitivity at 18.24 MHz.

In every ^{15}N spectrum (at 9.12 and 18.24 MHz) the side chain NH_2 resonance of ornithine was observed. Here, the significantly greater mobility of the side chain²⁷ relative to the backbone of the molecule ensures a sufficiently short correlation time to preclude signal nulling.

From the shift data presented above (Tables 2 and 3) it is possible to make a full assignment for the amide nitrogen resonances of gramicidin S. To a first approximation the data in Table 4 predict the amide nitrogen resonance of a given amino acid in a peptide chain to be independent of its position in the chain but to be influenced strongly by its substituents at the α carbon. We have not observed the amide nitrogen of ornithine in a peptide chain elsewhere but its shift can be calculated approximately⁵. Thus the relative amide nitrogen chemical

Fig. 3 ^1H Noise decoupled natural abundance ^{15}N NMR spectra (18.24 MHz) of gramicidin S (0.18 M in DMSO). Average accumulation time per spectrum was about 40 min. Both spectra are out of phase by 180°, that is, signals are inverted by the NOE. a, 47 °C; b, 18 °C.

Fig. 4 Correlation diagram of amide nitrogen resonances from gramicidin S. a, Predicted from model dipeptides (see text); b, observed from solution 0.23 M in DMSO; c, observed from solution 0.2 M in methanol

shifts of gramicidin S are predicted as the acetyl amino acid shifts (Table 2) minus 5.4 p.p.m. (Table 3). (This actually gives the amide nitrogen resonance as the C-terminal unit of an N-acetyl dipeptide.)

Although the patterns of observed and predicted chemical shifts are similar, the predicted ones are each substantially to higher field than the observed shifts as shown by the correlation diagram (Fig. 4). The reason for this is not yet clear, but it should be remembered that the predictions are from model dipeptides which include free carboxylic acid groups, whereas gramicidin S has side chain $-\text{NH}_2$ groups. A second possible source for the displacement in Fig. 4 is the unknown effect of constraining the peptide in a cyclic structure and introducing intramolecular hydrogen bonding between leucine and valine²⁵. Each of these effects is the subject of a continuing study.

For our study the amino acid and small peptide derivatives were prepared by standard methods. We used gramicidin J from *Bacillus brevis* (nagano) (Sigma) which has the same chemical structure as gramicidin S. ^{15}N NMR spectra were obtained from the Bruker HFX-90 (^{15}N at 9.12 MHz) and Bruker WH-180 (^{15}N at 18.24 MHz) instruments operating in the pulse-Fourier transform mode with ^1H noise decoupling. Samples were contained in tubes of outer diameter 10, 13 or 15 mm (HFX-90) and 25 mm (WH-180). Deuterium in the solvent or, in the case of aqueous (H_2O) or methanol (CH_3OH) solutions, deuterium oxide in a concentric 5-mm tube, provided the field-frequency stabilisation signal. D_2O and CD_3OD were not normally used as solvent in order to prevent exchange of deuterium for labile protons in the solute. Typical spectral accumulation times (HFX-90) were 5–10 h for 1-M solutions of amino acid derivatives with pulse flip angles about 30°, and pulses were repeated every 0.4 s. The higher magnetic field, larger sample volume and quadrature detection system of the WH-180 instrument provided an estimated increase in signal-to-noise of about 18:1 for a single pulse experiment, or a saving in time corresponding to a factor of about 300 for spectral accumulation, when compared with the HFX-90 even with 15-mm tubes.

The accuracy of the measured ^{15}N chemical shifts was limited by the digitisation of the transformed spectrum (2.4 Hz per point) and was about 0.3 p.p.m. for the HFX-90 and 0.15 p.p.m. for the WH-180. ^{15}N Chemical shifts were referenced to the

ammonium ion resonance from an external sample of $^{15}\text{NH}_4^+$ $^{15}\text{NO}_3^-$ 5 M in 2-N nitric acid.

^{13}C Spectra at 22.6 MHz were obtained with the HFX-90 instrument. Sample temperatures for the HFX-90 instrument were about 35 °C, and for the WH-180 instrument are estimated to be accurate to ± 3 °C.

We thank the Science Research Council for the HFX-90 spectrometer and Bruker Spectrospin AG for use of the WH-180.

letters to nature

Clustering of faint blue objects

PHOTOGRAPHS taken with the UK 48-inch Schmidt Telescope at Siding Spring, Australia using hypersensitised Kodak IIIaJ emulsions, record objects as faint as magnitude 23 in exposures of an hour. Most galaxies on the photographs are very faint and at, say 22 mag probably have redshifts $Z \sim 0.5$. At such large redshifts the K term is responsible for considerable reddening ($B-V \simeq +2$ mag) and it may perhaps not be expected that such blue sensitive emulsions would show much increase in the number of faint galaxies recorded as the limiting magnitude increases beyond about 21 mag. The number of objects does, however, seem to continue to increase significantly with limiting blue magnitude and the question therefore arises as to whether or not a substantial number of faint images are blue and if so, what objects do they represent and how are they distributed?

To examine this question a IIIaJ photograph of a region near the south Galactic pole has been compared with a red-sensitive photograph of the same region. Both plates reach very faint magnitudes and when viewed in a Zeiss comparator most images are similar on both plates—that is to say, are of neutral apparent colour. The outer parts of some relatively bright spirals are noticeably blue, the inner parts neutral. Among the faint objects (which are the vast majority) a significant minority, several per cent, are noticeably blue, and a smaller minority are noticeably red.

The positions of noticeably blue objects in an area 22 arc min square were measured by one of us (V.C.R.) and the distribution is shown on Fig. 1. There are 168 objects. Only objects for which images appeared on both red and blue plates were recorded in order to avoid the accidental inclusion of plate faults. The criterion of 'blueness' by which they were chosen in this way is of course arbitrary and subjective. They represent about 10% of all the images in that area of the photographs: that is to say they are the bluest 10% of the objects. At the magnification employed, $\times 13$, almost all the images appear stellar. Comparison with a similar IIIaJ photograph of the cluster Kron 3 near the SMC in which M. F. Walker has determined electronographic magnitudes to $B = 22.7$ shows that many, perhaps most, of the objects are $B = 22$ or fainter and the great majority are fainter than $B = 21$.

It is immediately apparent from Fig. 1 that the apparent surface distribution is non-random. There is a tendency to clustering and particularly for the occurrence of pairs. This is confirmed by Fig. 2, which shows the frequency distribution of the separations of each object from its nearest neighbour (histogram $O(V.C.R.)$). A Poisson distribution with the same average separation (45'') is shown, $P(45,168)$, for comparison. If the objects were uniformly distributed the average separation would be 100'' and so the observed distribution represents a concentration by a factor of five. It has a sharp peak at a much smaller separation than the average, at 10–20'', and a second broad maximum around 70''. It is fairly well represented by the sum of two Poisson distributions $P(20,102;77,66)$ in which two thirds of the objects have a mean separation of 20'' and the remaining third a mean separation of 77''. The first of these

Fig. 1 The apparent distribution of faint blue objects as measured by V.C.R.

Fig. 2 N is the number of faint blue objects per unit of $7''$ in θ . θ is the angular separation of each from its nearest neighbour. O (V.C.R.) is the distribution measured by V.C.R. corresponding to Fig. 1; O (M.R.S.H.) that measured by M.R.S.H. corresponding to Fig. 3. The latter's threshold was chosen more blue than the former's and thus the total number of objects is smaller (73 as against 168). $P(45,168)$ is a Poisson distribution with the same mean θ (45) and total N (168) as O (V.C.R.). $P(20,102;77,66)$ is the sum of two Poisson distributions with mean θ 20 and 77'' and total numbers 102 and 66 respectively.

distributions represents the preponderant number of pairs evident on Fig. 1.

In order to check the validity of the data, especially in view of its element of subjectivity, and to provide data for another region, M.R.S.H. similarly measured the positions of the bluest objects in a second region of the same size but separated by several degrees from the first. His result is shown on Fig. 3. The number of objects is smaller, 73 against 168, and it appears from a cross check by the two of us that M.R.S.H. set his

Fig. 3 The apparent distribution of faint blue objects as measured by M.R.S.H. in a region several arc degrees away from Fig. 1.

criterion at a bluer level than V.C.R.; thus Fig. 3 represents the distribution of the bluest 5% of the images. The same effects are again immediately apparent, however—some clustering and a preponderance of pairs. This impression is also confirmed by the histogram O (M.R.S.H.) in Fig. 2.

The non-random nature of the distribution makes it very unlikely that the objects are faint blue stars in the Galactic halo; they are almost certainly extragalactic. The faintness and star-like quality of the images indicate that they are distant, perhaps very distant, and compact. The blueness suggests that they are

not ordinary galaxies but lie in the range from very blue compact galaxies to quasars. Whatever they are the high degree of clustering, and especially the preponderance of pairs, appears to be significant. Taken together with a recent indication of an increase in the degree of clustering of galaxies with distance¹ this may be further direct evidence of an evolving universe.

Possible local variation of the Hubble constant in van den Bergh's calibration of Sc-type galaxies

IN an important series of papers for the determination of the Hubble constant, Sandage and Tammann¹⁻⁶ have concluded that the Universe is expanding in a remarkably uniform and isotropic way, with Hubble constant (H) $55 \pm 5 \text{ km s}^{-1} \text{ Mpc}^{-1}$. If true, this result is evidently crucial for all future cosmological models. As a consequence it should be tested and analysed in all possible ways. Their low H value is evidently based on their recalibration of the absolute magnitudes of the various luminosity classes of Sc-type galaxies based on two samples of nearby, and one sample of distant galaxies (Tables 3 and 4, ref. 5, and the Table, ref. 6).

Here we discuss some consequences of Sandage and Tammann's specific choice of absolute magnitudes, and to compare them with the calibration of van den Bergh⁷, which had been generally accepted in the literature.

Two preliminary remarks should be made here. First, starting from the data and calibration of Sandage and Tammann, de Vaucouleurs has analysed possible variations of the redshift distribution with supergalactic longitude and latitude, and discovered significant deviations from isotropy. Second, if one calculates H using only the Sc I galaxies, one does indeed

Table 1 Recalibration of Sandage and Tammann's data on sources in local supergalaxy anticentre direction using van den Bergh's absolute magnitudes

Sc classes	M_{ST}	M_{vdb}	$\alpha = H_{vdb}/H_{ST}$
I	-21.25	-20.0	1.778
I-II	-20.74	-19.7	1.614
II	-20.23	-19.4	1.466
II-III	-19.72	-18.9	1.459
III	-19.21	-18.3	1.521

find the same H at all distances, although Sandage and Tammann's unbiased data for Sc II anticentre galaxies (Tables 3 and 4, ref. 5), yield $\langle H \rangle = 77.6 \pm 6.0 \text{ km s}^{-1} \text{ Mpc}^{-1}$, which differs significantly from the result for Sc I anticentre galaxies (Table 2) $\langle H \rangle = 61.4 \pm 6.8 \text{ km s}^{-1} \text{ Mpc}^{-1}$ so that $\Delta H = 19.2 \pm 8.1 \text{ km s}^{-1} \text{ Mpc}^{-1}$ (Student's $t = 2.53$).

If, then, one accepts de Vaucouleurs' result (unpublished), that the overall motion of the local supergalaxy contributes significantly to the redshift distribution, one should concentrate discussion of the possible consequences for H determination of a recalibration of Sandage and Tammann's samples with van den Bergh's absolute magnitudes, on sources located in the anticentre of the local supergalaxy direction.

We do this in Table 1. Column 1 shows the Sc classes used in Sandage and Tammann's determination of H ; columns 2

Table 2 Comparison of values of H obtained for the new calibration, for the two samples described in the text

Sc-type	H_{ST} km s ⁻¹ Mpc ⁻¹	H_{vdb} km s ⁻¹ Mpc ⁻¹	H_{ST} km s ⁻¹ Mpc ⁻¹	H_{vdb} km s ⁻¹ Mpc ⁻¹
Sc I	61.40 ± 6.84	109.16 ± 12.16	51.73 ± 2.72	91.98 ± 4.83
Sc I-II	67.83 ± 9.59	109.48 ± 15.5		
Sc II	77.61 ± 5.99	113.70 ± 8.82		

and 3, the values of the corresponding absolute magnitudes used by them and by van den Bergh, column 4, the numerical factors by which the $H = v/r$ values of Sandage and Tammann should be multiplied, to pass to the corresponding values in van den Bergh's calibration, that is α in $H_{vdb} = \alpha H_{ST}$.

The calculations have been performed on all the unbiased anticentre galaxies in refs 5 and 6. For nearby galaxies we have used exactly the limit proposed by Sandage and Tammann to eliminate a possible bias, that is, for those with values of $\log v \leq 3.3$. The same has been done for distant Sc I galaxies—we have restricted the calculation (as prescribed by Sandage and Tammann) to the 40 anticentre objects with $\log v \leq 3.92$.

The results are summarised in Table 2. Column 1 shows the Sc classes analysed; columns 2 and 3, the corresponding H values obtained in calibrations by Sandage and Tammann and van den Bergh for the sample of 7 Sc I, 4 Sc I-II and 8 Sc II nearby unbiased anticentre galaxies. Columns 4 and 5 contain the respective H values for the unbiased sample of 40 distant anticentre Sc I galaxies.

We derive three conclusions from Table 2. The first is that Sandage and Tammann's calibration yields significant differences in the $\langle H \rangle$ values obtained with different types of nearby Sc galaxies—a fact difficult to reconcile with their own assumptions. The second is that van den Bergh's calibration, though possibly open to criticism, does not present this inconvenience, and yields a consistent $\langle H \rangle$ value for all classes of nearby Sc galaxies: $\langle H \rangle = 111.2 \pm 6.3$ km s⁻¹ Mpc⁻¹, for 19 objects. The third is that this latter value differs significantly from the distant Sc $\langle H \rangle$ value (that is, $\langle H \rangle = 92 \pm 5$ km s⁻¹ Mpc⁻¹) since we have $\Delta H = 19.2 \pm 8.1$ km s⁻¹ Mpc⁻¹.

If one accepts van den Bergh's calibration, this evidently yields a statistically significant decrease of H with distance, since for the hypothesis $H(\text{nearby}) = H(\text{distant})$, $t = 2.38$ ($P < 0.05$). Finally it should be noted that the existence of such a variation of H is independently supported by very recent determinations of the distance D of 29 Sc-type galaxies (12 of which belong to the preceding Sandage-Tammann sample) made on the 21-cm line at the Nançay Radiotelescope by Durand⁸ and Bottinelli *et al.* (unpublished). Indeed, if one divides Durand's result into two groups: the first with 15 objects at $D \leq 30$ Mpc and the second with 14 objects at $D > 30$ Mpc, one obtains $\langle H \rangle_1 = 95.2 \pm 11.0$ and $\langle H \rangle_2 = 63.5 \pm 5.4$ km s⁻¹ Mpc⁻¹.

Obviously, this possible variation of H with distance can be correlated with the angular anisotropy of H observed by Rubin, Ford and Rubin⁹, which has been confirmed on various types of source¹⁰. Independently of any specific interpretation (such as a variation of the redshift of photons passing through the radiation field of distant galactic clusters¹⁰, this conflict between the results of calibrations on the same sample by Sandage and Tammann and van den Bergh shows that further observational work needs to be done on this calibration problem.

We thank Drs L. Bottinelli, N. Durand, L. Gougenheim, J. Heidmann, G. Paturel, and Professor G. de Vaucouleurs for helpful discussions and advanced communication of their results.

Why there are no elliptical galaxies flatter than E7

It has long been known¹⁻³ that the flattest elliptical galaxies observed are of type E7, corresponding to an axial ratio of 3.33:1 whereas SO and spiral galaxies are seen with axial ratios up to 20:1. We show, using Maclaurin spheroid models, that an initially spherical protogalaxy, composed entirely of stars, will always relax after a dissipationless collapse to an equilibrium configuration with $\epsilon \equiv 1 - (c/a) \leq 0.70925$, where a, c are the semi-major, semi-minor axes. This happens regardless of original angular momentum of the galaxy, and is in remarkable agreement with the maximum observed flattening of elliptical galaxies.

According to the standard cosmological picture, protogalaxies begin as small density perturbations at recombination, expand to a maximum radius and recollapse, reaching the maximum collapse point at $t = T_c$. By $t = T_c/2$, the protogalaxy has acquired its angular momentum by tidal interaction⁴ or turbulence⁵. At this time, we assume the protogalaxy to be a uniformly dense sphere, of mass M , of initial radius a_i

Fig. 1 Ellipticity ϵ , semi-major and semi-minor axes (a, c) of the equilibrium elliptical galaxy as a function of $t_1 = |T_{rot}/W|$. The curve $\epsilon(t_1)$ is symmetrical with respect to $t_1 = 0.5$.

rotating uniformly with angular velocity Ω_i . There are initially no random velocities. To characterise the angular momentum of the protogalaxy, we introduce the convenient parameter t_i as the ratio of the rotational kinetic energy T_{rot} of the sphere to its potential energy W :

$$t_i = \left| \frac{T_{\text{rot}}}{W} \right| = \frac{\Omega_i^2 a_i^3}{3GM} \quad (1)$$

The initial binding energy of the protogalaxy is:

$$E_i = W_i (1 - t_i) = -\frac{3}{5} \frac{GM^2}{a_i} (1 - t_i) \quad (2)$$

If star formation occurs early and is completed by $t = T_c/2$, the protogalaxy undergoes a dissipationless collapse¹³, relaxes violently⁶ and settles into an equilibrium configuration by $t = 3T_c/2$ (ref. 7). Violent relaxation tends to isotropise random velocities, as suggested by an N -body calculation including infall and tidal effects⁸, and by fits to the light distributions of elliptical galaxies using King's⁹ models which have an isotropic distribution of random stellar velocities. We adopt as the simplest model for the equilibrium galaxy a Maclaurin spheroid in virial equilibrium with uniform rotation and isotropic pressure. Although real elliptical galaxies have dense cores and exhibit differential rotation the ellipticities predicted by numerical models of elliptical galaxies and Maclaurin spheroid models are in reasonable agreement¹³. The energy of the Maclaurin spheroid is

$$E_{\text{eq}} = \frac{W_{\text{eq}}}{2} = -\frac{3}{10} \frac{GM^2}{a_{\text{eq}}} \frac{\sin^{-1}e}{e} \quad (3)$$

where eq denotes 'equilibrium' and

$$e = \left[1 - \left(\frac{c}{a} \right)^2 \right]^{1/2}$$

Since there is no dissipation, $E_i = E_{\text{eq}}$ or

$$2(1 - t_i) = \frac{\sin^{-1}e}{e} \frac{a_i}{a_{\text{eq}}} \quad (4)$$

Angular momentum conservation gives

$$(T_{\text{rot}})_{\text{eq}} = \left[\frac{a_i}{a_{\text{eq}}} \right]^2 (T_{\text{rot}})_i = \frac{3}{5} \frac{GM^2}{a_i} t_i \left[\frac{a_i}{a_{\text{eq}}} \right]^2 \quad (5)$$

The rotational kinetic energy of a pressure supported equilibrium Maclaurin spheroid is¹⁰

$$[T_{\text{rot}}]_{\text{eq}} = \frac{3GM^2}{10a_{\text{eq}}e^3} [(3 - 2e^2) \sin^{-1}e - 3e(1 - e^2)]^{1/2} \quad (6)$$

Combining equations (4) to (6):

$$t_i(1 - t_i) = \frac{1}{4} \frac{\sin^{-1}e}{e^4} [(3 - 2e^2) \sin^{-1}e - 3e(1 - e^2)]^{1/2} \quad (7)$$

which for a given t_i , can be solved for e ; a_{eq} and c_{eq} are then found using equation (3) and (4). The results are shown in Fig. 1. Note that equation (7) is symmetrical about $t_i = 0.5$ which corresponds to an ellipticity of 0.70925. For $t_i < 0.5$ (probably in the majority of cases), the galaxy gets flatter on adding angular momentum, but past $t_i = 0.5$ adding angular momentum makes the equilibrium galaxy rounder. Given our model, no elliptical galaxy can be flatter than an E7, no matter how fast it rotates initially. This surprising fact is due to the equilibrium Maclaurin spheroid blossoming to infinite size with only a finite amount of angular momentum. At $t_i = 1$,

the galaxy has only $\sqrt{2}$ times the angular momentum of one at $t_i = 0.5$ (initially in virial equilibrium), but because the total kinetic energy has increased to equal the potential energy, the binding energy becomes 0, and a_{eq} and c_{eq} become infinite. For $t_i > 1$, the galaxy becomes unbound. Another symmetry about $t_i = 0.5$ is found in numerical experiments by Bouvier and Janin¹¹ who found that spherical systems with t_i (random) = 0.25 and t_i (random) = 0.75 have comparable amounts of violent relaxation. The system with the least violent relaxation is the E7 galaxy with $t_i = 0.5$.

Any initial random velocities, or any net expansion or contraction of the initial spherical protogalaxy, can only decrease the ellipticities, since all these effects decrease the binding energy without affecting the angular momentum; thus the upper limit of $\epsilon = 0.70925$ is left intact. Maclaurin spheroids become dynamically unstable at $|T_{\text{rot}}/W| = 0.273$ ($e = 0.95289$ or $e = 0.69668$ (ref. 11)). This is close enough to our maximum value of 0.70925 not to affect our conclusions. Real stellar systems with $|T_{\text{rot}}/W| \gtrsim 0.14$ ($e > 0.81267$ or $e > 0.41727$) may, however, be unstable to bar instabilities¹². Phase mixing may smear the bar out in time so as to leave a more centrally condensed axisymmetric galaxy with $|T_{\text{rot}}/W| \sim 0.14$. It is not clear, however, that the final ellipticity is changed greatly by this process.

Our result depends on the assumption of an initially spherical state and of conservation of energy and angular momentum. The final Maclaurin spheroid can be as flat as one wants if energy is dissipated—which we believe is the mechanism for the formation of a disk spiral galaxy¹³—or if the initial state is non-spherical. To investigate this, we write:

$$E_{\text{eq}} = \alpha E_i \quad (8)$$

$$[T_{\text{rot}}]_{\text{eq}} = \beta \left(\frac{a_i}{a_{\text{eq}}} \right)^2 [T_{\text{rot}}]_i \quad (9)$$

$$\text{and} \quad W_i = -\frac{3}{5} \frac{GM^2}{a_i} \frac{\sin^{-1}e_i}{e_i} = -\frac{3}{5} \frac{GM^2}{a_i} \gamma \quad (10)$$

This has the consequence of multiplying the left hand side of equation (7) by $\alpha\beta\gamma$. Let $F = 4\alpha\beta\gamma t_i(1 - t_i)$. Figure 2 shows ϵ_{final} as a function of F . $\epsilon_{\text{initial}}$ as a function of F is also shown in the case when the energy E and the angular momentum J are conserved. There are several points to be made:

(1) For the final state to be a flat disk $F = \pi^2/4$, so if J is conserved and the initial state is spherical then the dissipation must be large enough so that $E_f/E_i \geq \pi^2/4$.

(2) In the tidal interaction picture, the angular momentum

Fig. 2 Ellipticity ϵ_{final} of the equilibrium elliptical galaxy as a function of $F = 4\alpha\beta\gamma t_i(1 - t_i)$. The initial ellipticity ϵ_i is also given as a function of F when energy and angular momentum are conserved.

is gained over a time scale $\sim T_c/2$, so for $t_i \gtrsim 0.5$ the original spherical shape may become somewhat flattened in the process of gaining angular momentum, which would have the consequence of increasing the maximum ellipticity ϵ_m . For example, for $\epsilon_i = 0.5$, Fig. 2 shows that for a dissipationless collapse, $\epsilon_{max} \sim 0.83$ ($F = 1.48$). The limiting case is again given by $F = \pi^2/4$ when $\epsilon_i = \epsilon_m = 1$.

In conclusion, with a roughly spherical shape initially and a dissipationless collapse conserving angular momentum, we expect no equilibrium elliptical galaxies flatter than E7 regardless of the original angular momentum. The remarkable agreement of this with the maximum observed ellipticity would seem to argue that this very simple picture may be a close approximation to reality.

Galactic dust lanes and lunar soil

It has been proposed by McCrea¹, Shapley² and Hoyle and Lyttleton³ that passages of the Solar System through interstellar clouds have appreciable effects on the Earth. McCrea argues that the recurrence of ice epochs⁴ every ~ 250 Myr coincides with the passage of the Solar System through a galactic spiral arm approximately every 10^8 yr. We report here studies on the character and grain-size distribution of texturally-mature lunar soils which support these views. The evidence shows the flux of micrometeoroids ($\lesssim 10^{-6}$ g) at the lunar surface has remained in quasi-equilibrium near the present-day value over the past 2×10^9 yr, but that significant increases have occurred. Three near-cyclical enhancements are superimposed on the drill core stratigraphy, with separations of $\sim 10^8$ yr. The magnitudes, durations, and periodicity of the flux increases suggest their origin may be the passage of the Solar System through dust lanes in the galactic spiral arms.

It has been noted⁵ that a segment of the cumulative grain-size distribution of "texturally-mature"⁶ lunar soils closely parallels the present meteoroid flux distribution in the soil grain-size range 44–177 μ m, at the maximum concentration of impact-derived constructional glass particles, or "agglutinates"^{7,8}. We believe that this segment of the soil distribution provides information on the meteoroid flux distribution that produced it.

Most of the kinetic energy in the present meteoroid flux⁹ is in particles of masses $< 10^{-6}$ g which strike the lunar soil at a

velocity of ~ 20 km s⁻¹ and generate enough heat to fuse a volume of soil. Some melt is lost as spray during crater excavation, but morphological information in the form of ring- (Fig. 1) or bowl-shaped agglutinates¹⁰ suggests that only one large agglutinate particle is formed by any one micrometeoroid impact. Thus the parallelism between grain size and meteoroid flux is understandable: one simply mirrors the other. Experimental data on the ratio of mass of the melt to mass of the meteoroid at 20 km s⁻¹ is lacking, but theory⁹ suggests that an agglutinate represents ~ 5 times the mass of the impacting micrometeoroid at 20 km s⁻¹. Using mean agglutinate diameters and a particle density of 3.1 g cm⁻³ the parallel segment of the soil curve converts to a micrometeoroid mass range of 0.08×10^{-6} – 2.0×10^{-6} g.

A meteoroid distribution is $N = am^\beta$, where N is the total number of particles larger than mass m , a is the intercept and β is the slope of a plot of log flux against log mass for masses larger than $\sim 10^{-7}$ g (refs 9 and 11). We convert the bulk grain-size distribution for the 45–177- μ m range from weight % retained in sieves to particle number equivalents assuming spherical particles. The numbers of particles in five size intervals are normalised to the total number, and we construct a cumulative particle number frequency distribution. Using equivalent meteoroid masses and cumulative particle numbers in log-log form, a linear least squares fit gives β . But a (which gives total flux) cannot be found without knowing the meteoroid exposure time of the soil. We derived β for 61 samples—12 surface soils and 49 from the Apollo 15 deep drill core. In all cases the linear fit explains $> 97\%$ of the variance, thus demonstrating a strong linear dependence between log N and log m .

Soils from the lunar surface should give β estimates near the modern flux value derived from other methods, thus offering an independent test of the model. The present meteoroid flux in our mass range has $\beta = -1.213$ (ref. 9). Estimates of β for the surface samples range from -1.266 to -1.142 with a mean of -1.213 ± 0.039 . A one-tailed t test indicates no significant difference between the modern β value and our estimates from

Fig. 1 A ring-shaped agglutinate from the lunar soil. The agglutinate is approximately 180 μ m in diameter.

Fig. 2 Estimates of β as a function of depth in the lunar soil. Estimates of β seldom exceed the modern flux value and are not correlated with the soil stratigraphy. The top half of the stratigraphic column shows major units only—the bottom half shows all units identified.

the surface soils ($t_{0.05} = 2.201 > 0.043$, d.f. = 11). That is, the model works.

Large meteoroids produce ejecta blankets of sufficient thickness and extent to survive as layers. This creates three interpretation problems: (1) inverted stratigraphy may appear in the record¹²; (2) old agglutinates may survive excavation from an earlier layer; and (3) the soil accumulation rate is nonlinear^{8,13}.

First, inverted stratigraphic sequences of small thickness will not destroy regular trends in the data, but will increase deviations about the trend. The range in β values is not affected. Second Lindsay⁵ investigated agglutinate survival under reworking and found most pre-existing agglutinates are destroyed in excavation by layer-forming events (that is, crushed to sizes $\lesssim 15 \mu\text{m}$, below our range). Third, soil accumulation rates are nonlinear^{8,13}, but modelling the growth requires assumptions of the meteoroid flux history, so it is best to model linear accumulation. The age of the substrate¹⁴ and total soil thickness at the Apollo 15 site¹⁵ give an average accumulation rate of $1.35 \times 10^{-7} \text{ cm yr}^{-1}$. Nonlinear soil models¹³ fortunately give similar rates for this time period. Since our sampling interval is 0.5 cm our time resolution is $\sim 4 \times 10^6 \text{ yr}$.

The core samples cover a depth of 120–240 cm in known stratigraphy (Fig. 2). Estimates of β for these samples range from -1.199 to -1.381 with a mean of -1.248 ± 0.036 . The data do not show a monotonically decreasing flux distribution but suggest a quasi-steady-state background level near the modern flux value, with enhancements superimposed. Below 180 cm the deviations are a series of disordered 'spikes'; above 180 cm three regular deviations each extend over 15–20 cm of the record. Each cycle crosses several stratigraphic units, indicating that the β variations have extra-lunar, time-dependent sources, rather than being determined by independent depositional processes operating on individual stratigraphic units.

Micrometeoroid experiments on the Pioneer 8, 9, 10 and 11 spacecraft^{18,19} show the asteroid belt is not a small particle source. Unless the particle populations and dynamics in the Solar System were quite different 1–2 eons ago, we suggest that the flux enhancements are not redistributions of matter by asteroidal collisions. We propose the enhancements record passages of the Solar System through dense interstellar clouds, plus active cometary episodes. These two sources may be manifestations of the same event: namely the passage of the Solar System through compression lanes in the arms of the Galaxy¹ and the concomitant generation of comets and their subsequent mass loss to the Solar System²⁰.

Lyttleton^{20,22,25} suggests that comets are "new" members of the Solar System formed by the interaction of the Sun with interstellar clouds. The Sun encounters dense clouds ($\sim 10^{-19} \text{ g cm}^{-3}$) in "compression lanes" of interstellar matter in the galactic spiral arms²⁰. Mass loss from long-period comets so

formed could enhance the small particle flux for 10^7 – 10^8 yr (ref. 17).

Hartung and Störzer¹⁶ suggest the modern small particle flux is increasing due to activity by Comet Encke. A micrometeoroid detector on the Heos-2 spacecraft²¹ shows that Comet Kohoutek deposits small particles into the inner Solar System. Lyttleton²³ suggests that particles $\lesssim 10^{-6} \text{ g}$ are lost from comets due to the solar wind. Since comets have masses of 10^{17} – 10^{20} g and lose $\gtrsim 10^{-4}$ of this in each solar encounter^{20,22}, one comet could increase the particulate material density within the orbit of Jupiter²⁰ by $\sim 3 \times 10^{-24} \text{ g cm}^{-3}$ if the debris is in the ecliptic. For matter collected by the Moon at 20 km s^{-1} , the surface flux would increase by $\sim 10^{-10} \text{ g cm}^{-2} \text{ yr}^{-1}$ above the present level of $1.2 \times 10^{-9} \text{ g cm}^{-2} \text{ yr}^{-1}$ in small particles^{9,11,23,24}. Further flux enhancements are possible for cometary periods which are short compared with the Solar System debris retention time¹⁷. Such enhancements could explain brief flux excursions. The 'peak' at $\sim 200 \text{ cm}$ corresponds to a small particle flux increase of ~ 15 times the present value.

The speed²⁶ of the Sun through compression lanes is 5 – 24 km s^{-1} , so cloud densities as above give enhancements $5 \times 10^{-8} \text{ g cm}^{-2} \text{ yr}^{-1}$. Although interstellar clouds have variable constitution, "typical clouds" contain $\approx 1\%$ grains by mass^{27,28}. For an encounter speed of 20 km s^{-1} , these particles striking the Moon would increase the small particle flux by $\sim 10^{-8} \text{ g cm}^{-2} \text{ yr}^{-1}$. So such encounters are numerically capable of producing the flux changes deduced from lunar soil parameters.

From 120 to 180 cm in the core tube the β variations are smooth, cyclical deviations from the present-day value. Although it is difficult to correlate depth with age exactly, the three cycles have periodicities of 1×10^8 – $2 \times 10^8 \text{ yr}$ and comparable durations. On this basis, the cycles cover an age 0.9×10^9 – $1.5 \times 10^9 \text{ yr}$ (all Precambrian), so unfortunately our data cannot be compared with known glacial epochs. McCrea¹ points out that the Solar System crosses a spiral arm every 10^8 year or so, taking $\sim 10^6 \text{ yr}$ to cross the compression lane and spending a total of $\sim 10^7 \text{ yr}$ in the arm. This agrees well with our estimates of β cycles in the soil, except for their longer durations ($\sim 10^8 \text{ yr}$) which may be due to mass loss to the inner Solar System by long-period comets born in such encounters.

Jupiter's atmospheric circulation

By numerical integration of conventional meteorological equations at appropriate parameter values we have been able to reproduce most of the major characteristics of the Jovian atmosphere.

The axisymmetry and scale of the bands, the oval-shaped disturbances, the waves and the Great Red Spot are all essentially characteristics of turbulent barotropic vorticity exchanges in a rapidly rotating planetary atmosphere. They are produced by the interaction in a spherical domain of a two-dimensional (horizontal) turbulent cascade and Rossby wave propagation, a process that we shall refer to as global turbulence. This interaction occurs at a length scale $L_B = \pi(2u/\beta)^{1/2}$, where u is a measure of the zonal velocity and β is the northward gradient of the Coriolis force, that closely matches the observed size of the bands. This hypothesis has been verified by solutions obtained for a stochastically forced barotropic equation, see for example Fig. 1.

The complete Jovian thermodynamical system can be reasonably well reproduced by using a standard (that is, Phillips's) terrestrial general circulation model under Jovian parameter conditions (see Fig. 2, for example). Apart from the characteristic banded structure the solutions also reveal the existence of an intra-jet circulation or gyre in which the flow resembles that surrounding the Great Red Spot. The planet also seems to have a heat transfer (index) cycle with a 4 to 5-yr period that accounts for long term variability. Clouds are produced by vertical circulation cells induced by frictional Ekman pumping.

Our theoretical flows suggest that the Great Red Spot can be thought of as essentially the core of an intra-jet circulation or as an eddy of global turbulence (as defined above). Like the ovals,

Fig. 1 An example of simulated Jovian turbulence. Sphere contains stream function contours with negative values shaded by 1/4 of grid points. Profile of longitudinally averaged zonal flow has a scale of 100 m s^{-1} in right-hand side diagram. State is transient and early in atmospheric evolution to final form. Although more orderly than final state it illustrates basic elements more clearly. A cine film of this solution is available on request.

Fig. 2 The global circulation as given by a terrestrial general circulation model integrated in the Jovian parameter range. Calculations were made over a limited sector and repeated for global display. Model is not valid at the equator.

the Great Red Spot plays an important role in the energy cascade that maintains the multiple zonal currents. The persistence of the Great Red Spot is due to the fact that (1) energy cascades toward larger scales in two-dimensional turbulence and (2) under the appropriate conditions large intra-jet circulations such as that forming the Great Red Spot are an integral part of this type of multiple-jet global circulation.

Thus Jupiter's atmosphere seems to have the same dynamical ingredients as the terrestrial atmosphere and ocean. The processes occur on different scales, however, and act in different proportions. As in the terrestrial and Martian systems, baroclinic instability again seems to be the primary energy conversion process. A complete description of the meteorology of Jupiter and Saturn has been submitted for publication elsewhere.

Noble gases in an Hawaiian xenolith

THE noble gas record in meteorites and lunar samples has been the subject of many investigations aimed at determining their age, the history of their exposure to cosmic rays and to the solar wind, and the early chronology of events in the Solar System (see review in ref. 1). Information on the latter is contained primarily in the isotopes of xenon, where the decay products of extinct ^{129}I and ^{244}Pu provide a record of the synthesis of elements and the early history of planetary solids (see review in ref. 2). The occurrence of radiogenic xenon in CO_2 well gas from Harding County, New Mexico is the only clear evidence that extinct radioactivities were present in the early history of the Earth^{3,4}, but the suggestion that this radiogenic xenon had been brought near the Earth's surface in hot magmas was not confirmed by recent analyses of xenon in lava rock from this region⁵.

The present investigation of noble gases in a volcanic xenolith containing high-purity inclusions of liquid CO_2 was undertaken to see if radiogenic xenon might be associated with

Table 1 Concentrations of noble gases in xenolith

mantle-derived CO₂ (ref. 6) and to see if the abundance pattern of noble gases within the Earth is represented by the noble gases trapped in glassy margins of certain deep-sea basalts^{7,8}. Two relatively large samples were taken from the interior of a large peridotite xenolith (≈0.5 kg) which had been brought to the surface by the 1801 Kaupulehu flow of the Hualalai volcano, Hawaii. The xenolith is composed of large olivine crystals (≈1–10 mm), which have been shown by density measurements and X-ray analysis to be rich in magnesium, approaching forsterite. The Hawaiian xenoliths are characterised by an abundance of inclusions of liquified CO₂, up to 3% by volume (0.5% by weight)⁹. These inclusions have been shown to contain radiogenic ⁴He and ⁴⁰Ar with a low ⁴He/⁴⁰Ar ratio as might be generated from a source of chondritic composition¹⁰.

To ensure complete autonomy of samples and to guard against the possibility of a systematic error, as might arise from 'memory' effects in the system, the two samples were analysed several months apart. Samples of other material were analysed in the interim period. The samples were mounted in the upper chamber of a water-cooled quartz extraction bottle, the pressure reduced to ≈10⁻⁹ mmHg, and the system blank measured by analysing gases generated in heating the new, empty molybdenum crucible to the highest temperature (≈1,700 °C) to be used in extracting gases from the sample. When the system blank had reached an acceptable level, a system blank for the low extraction temperature (600 °C) was determined, and then the sample was dropped into the crucible for extraction of gases. The gases were collected and analysed at the two extraction temperatures, first at ≈600 °C and then at ≈1,700 °C, at which the sample completely melted. The procedures used in our laboratory for calibration of the mass spectrometer and for extraction, clean-up, and analysis of noble gases have been described previously¹¹.

The concentrations of noble gases found in these samples are presented in Table 1. The gas concentrations were measured by the 'peak height' method, and are estimated to have an error of ±20%, except that ⁴He may have a systematic error due to leakage of helium through our glass vacuum system or through our glass air standards. To compare the abundance pattern of non-radiogenic noble gases in the xenolith with that in other terrestrial materials, we define a fraction factor, f^m , relative to ³⁶Ar,

$$f^m = ({}^m\text{X}/{}^{36}\text{Ar})_{\text{sample}}/({}^m\text{X}/{}^{36}\text{Ar})_{\text{air}} \quad (1)$$

where X represents a non-radiogenic noble gas isotope of mass number, m . For atmospheric noble gases¹² $f^m \equiv 1.00$ at all values of m , and, for all samples, $f^{36} \equiv 1.00$.

Figure 1 compares the values of f^m for noble gases in the xenolith with values of f^m for noble gases in Fig Tree Shale¹³ and in an enstatite melt which equilibrated with atmospheric noble gases¹⁴. The relative abundances of noble gases in Fig Tree Shale show the effect of preferential adsorption of the heavier noble gases^{15,16}, and the gases in the enstatite melt show that a solution of noble gases in melts in equilibrium discriminates against incorporation of the larger atoms. The abundance pattern of Ne, Ar and Kr in the xenolith is very close to that predicted by Kirsten¹⁴ for an enstatite melt which

has equilibrated with a gas reservoir having the relative abundances of Ne, Ar, and Kr that exist in the present atmosphere¹². For Xe the trend is reversed, however, and the xenolith has approximately 10 times more Xe than expected in a melt which has equilibrated with atmospheric noble gases. An apparent excess of Xe in the xenolith can be explained in terms of the selective depletion of atmospheric Xe by adsorption on shales^{13,15,16}. In view of the fact that Hawaiian basalt magma and xenoliths may come from depths as great as 60 km (ref. 6), the abundance pattern of noble gases in the xenolith (Fig. 1) suggests that the relative abundances of Ne, Ar, and Kr in the atmosphere may be a fair representation of noble gases which equilibrated with the mantle, but the Xe/Ar ratio in the mantle may be about an order of magnitude higher than the Xe/Ar ratio in the atmosphere. Thus, the abundance pattern for the total terrestrial inventory of noble gases seems to be very similar to that in typical chondrites, as has been suggested earlier from studies of noble gases on shales^{13,15,16}.

Fig. 1 A comparison of the noble gas abundance pattern in xenolith (●) with that in air (△)¹², in Fig Tree Shale¹³ (□), and in an enstatite melt¹⁴ (○), which has equilibrated with atmospheric noble gases.

The isotopic compositions of the noble gases released from the xenolith at 1,700 °C are given in Table 2, together with the isotopic composition of atmospheric noble gases. Xenon displays a clear excess of ^{129}Xe and a small excess of ^{136}Xe which is too low for a determination of the fission yields. The isotopic composition of the non-radiogenic xenon seems to be atmospheric, and the isotopic compositions of the other noble gases reveal no anomalies, except for radiogenic ^{40}Ar . The relatively high concentrations of ^{40}Ar interfered with measurements of other isotopes of argon and neon. The high beam intensity of $^{40}\text{Ar}^+$ ions caused a rapid build-up of 'memory' peaks at ^{36}Ar and ^{38}Ar , and $^{40}\text{Ar}^{2+}$ ions interfered with the ^{20}Ne measurement. For these reasons the isotopic composition of neon is not reported in Table 2, and only upper limits are given for the $^{38}\text{Ar}/^{36}\text{Ar}$ ratio.

The 4.5% enrichment of ^{129}Xe is greater than that observed in any well gas⁴ except in the CO_2 gas from Harding County, New Mexico, and the ^{129}Xe enrichment here is almost twice as large as that first observed³ in the CO_2 well gas. It should be stressed again that there were no indications during the analyses of memory or contamination at mass number 129, and we are confident that the ^{129}Xe anomaly is real. Possible origins for excess ^{129}Xe in

use of the noble gases in the xenolith to decipher the abundance pattern of noble gases within the Earth.

We wish to thank Professor H. W. Green II, for providing us with the xenolith sample. This research was supported by a grant from the US NSF.

The isotopic compositions of atmospheric Ar, Kr and Xe are from refs 17, 18 and 19, respectively.

CO_2 well gas have been considered elsewhere³, and the conclusion that this represents the decay product of extinct ^{129}I applies equally well to the xenolith sample. The xenolith sample thus represents the first terrestrial rock in which the decay product of an extinct radioactivity has been identified.

The site of the radiogenic ^{129}Xe in the xenolith was not determined, but the report of radiogenic ^4He and ^{40}Ar in the inclusions of xenoliths¹⁰ and the reports⁴ of radiogenic ^{129}Xe in CO_2 well gas suggest that we may be seeing 'orphan' ^{129}Xe , that is, radiogenic ^{129}Xe from an external reservoir rather than radiogenic ^{129}Xe produced within the xenolith by the decay of ^{129}I . Green⁶ has suggested the possibility of a CO_2 -charged asthenosphere as a source for the CO_2 -rich fluid inclusions in Hawaiian xenoliths. His model implies that the solid Earth is effectively capped against diffusive outgassing by the CO_2 asthenosphere, a result which may account for the terrestrial association of radiogenic ^{129}Xe with CO_2 . The presence of this decay product of ^{129}I ($t_{1/2} = 17 \times 10^6$ yr) in the xenolith is further evidence that the formation of the Earth did not appreciably postdate the formation of meteorites. It also indicates that the xenolith contained juvenile noble gases from the interior of the Earth, and thus lends credence to our

Bottom sliding of a glacier measured from the surface

We have measured the sliding motion at the bottom of a glacier from the surface of the ice. Fleming Glacier in the Antarctic Peninsula is a fast flowing polar glacier, more than 1,000 m thick, feeding the Wordie Ice Shelf. Observations indicate that up to a third of its surface velocity is due to the bottom layers of ice sliding over the bed. Previous measurements of the bottom sliding of glaciers have been confined to tunnels or boreholes that have reached bed-rock^{1,2}; sliding velocities have also been calculated indirectly by using assumptions about the internal deformation of ice³. Results obtained by our method can help to test theories of basal sliding⁴ and should give insight into the mechanism and consequences of surges in glaciers and ice sheets⁵.

The surface velocity can be considered to consist of two components, one representing deformation of ice in the body of the glacier and the other representing basal slip. Conventional optical survey using fixed rock as a reference was used to give the sum of both components of the surface velocity. A radio-echo technique⁶ gave the surface velocity relative to a layer that reflected electromagnetic waves—evidently from a level close to the base of the ice. Since this velocity differed from the survey velocity, it was inferred that the reflecting layer was embedded in the ice. The radio-echo method thus measured only the deformation component of the surface velocity, and the difference between the survey and radio-echo velocities represented the bottom sliding velocity.

Walford⁷ tried the radio-echo technique on Fleming Glacier and concluded that the radio-echo velocity agreed, within his limits of error, with the surface velocity determined by optical survey. We repeated the experiment, at a site within 1 km of Walford's site, in January 1974, but over a longer time to increase accuracy. This time there was a significant difference between the survey and radio-echo velocities⁸. In December 1974, therefore, we investigated

Table 1 Observed surface velocities on Fleming Glacier

	Date 1974	1		2		3	
		m yr ⁻¹	Direction	m yr ⁻¹	Direction	m yr ⁻¹	Direction
Survey velocity	Jan.	201 ± 20	284 ± 5°	175 ± 4	272 ± 5°	146 ± 4	277 ± 5°
	Dec.	201 ± 4	283 ± 5°				
Radio echo velocity	Jan.	138 ± 5	287 ± 1°	113 ± 7	272 ± 1°	139 ± 7	271 ± 1°
	Dec.	142 ± 11	277 ± 1°				
Sliding velocity	Jan.	62 ± 25	284 ± 5°	64 ± 11	272 ± 5°	7 ± 11	277 ± 5°
	Dec.	59 ± 15	283 ± 5°				

Relative velocity between sites 1 and 2 in December 1974 was 29 ± 4 m yr⁻¹ at $272 \pm 1^\circ$. The direction of the sliding velocity has been taken to be that of the survey velocity.

this same site and also two other sites on a flowline upstream from it, to resolve the apparent discrepancy. Figure 1 shows the radio-echo ice thickness profile through the sites occupied in December 1974, and Table 1 gives a summary of the results from the two seasons' work.

The optical survey was carried out by a method of resection. Six permanent reference objects on surrounding mountains were intersected from each end of a baseline 417.45 m long in January 1974, and 5,552.66 m long in December 1974. Subsequent resection of these points gave the movement of each site (J. L. W. Walton, personal communication). A period of about 16 d was necessary between resections to obtain the required accuracy. The change in distance between sites 1 and 2 was measured by a pair of MRA-3 tellurometers, which over a period of 14 d gave the relative velocity between the sites. This agreed with the difference between observed surface velocities at the two sites.

We used a modified Scott Polar Research Institute Mark IV radio-echo sounder to record the bottom-echo fading pattern only. It operated at 35 MHz in January 1974 and at 60 MHz in December 1974. Fading patterns over an area 11×2.5 m were generated by moving the aerial in a series of parallel lines along a track 25 cm above the surface of the snow. The patterns were calibrated with marks representing distance moved from a reference stake fixed in the surface of the glacier. The displacement of successive patterns relative to the stake over a period of days, was measured by comparing the position of distinctive features in the pattern with the distance marks. Values from parallel runs were averaged to give the velocity component along the track; a maximum error of 0.5%, resulting from the difference in angle between the survey velocity and the

alignment of the radio-echo track, can be neglected. Radio-echo velocities were obtained from fading patterns taken over periods of up to 10 d.

Table 1 shows that there is excellent agreement between the January and December results at site 1. Walford's radio-echo velocity at his site (close to our site 1) of 139 ± 11 m yr⁻¹ along $260 \pm 10^\circ$ also agrees with ours, indicating that differences between survey and radio-echo velocities are significant, and due to sliding of the glacier over its bed. Results from site 2 show a similar behaviour, but site 3 seems to have no sliding component. We are not yet in a position to determine whether there really was no sliding at site 3. If sliding did occur but the radio-echo reflecting surface was the actual glacier bed, rather than a layer embedded in the ice near the base, this would account for the anomaly. If the reflecting surface was the true glacier bed it is to be expected that the radio-echo velocity would be the same as the survey velocity.

An ice mass can only slide over its bed if the temperature of the basal ice is at its pressure melting point. Using measured values of the ice temperature at a depth of 10 m (-12.6°C), the observed annual accumulation of snow (100 g cm^{-2}) at site 1 and the surface velocity transformed to an equivalent basal heat flux⁹, steady-state models¹⁰ indicate that the basal ice at site 1 is probably at the melting point. This calculation cannot, however, be sufficiently precise to distinguish between basal ice temperatures at the three sites.

We noticed that the relationships between some features in the fading patterns changed with time. This may be attributed to a gradual deformation of the geometry of the reflecting layer near the base of the ice. Although the nature of the reflecting layer is unknown, it evidently reflects more electromagnetic energy than the bedrock. If the reflecting layer and the bedrock reflected nearly equal amounts of energy, then the received signal, being a combination of echoes from both reflecting surfaces, would be sensitive to relative motion between them. In this case, the fading patterns would not remain recognisable after a period of time. The reflecting layer could be either morainic material², or possibly a layer of ice at its pressure melting point.

I thank the British Antarctic Survey for support, J. L. W. Walton and others for carrying out the optical surveys, all colleagues who helped both in the field and in support, and Dr C. W. M. Swinbank for suggesting the experiment.

An experimental approach to lithification textures

ALTHOUGH observations on changes taking place during the compression of monominerals have been published^{1–3}, little or no information exists on the textural aspects of compression affecting granular sediments. The main reason for this lack of textural information is presumably a technical problem. Ever since the pioneering investigations conducted by Bridgman, equipment used in high pressure experiments in geology has consisted of hydraulic cylinders in combination with completely closed, thin-walled test-tube bombs compressed by the surrounding oil in the hydraulic system^{4,5}. The triaxial cell used in tectonic studies, allowing control over the three stress directions, uses massive samples jacketed to prevent the pressure medium from direct contact with the sample⁴. Triaxial studies have been performed only with massive samples, that is, already lithified rocks. No tests have yet been described involving thin sectioned samples of granular sediments subject to compression. Essentially, such experiments would reveal the mechanical aspects of the burial of natural sediment.

Fig. 1 *a*, Lithification texture produced experimentally during dry compression of various carbonate bioclasts (fragments of clam shells, echinoids, coralline and encrusting algae). *b*, Thin sectioned natural sample (bioclast grainstone). Compare the nature of grain contacts and the absence of porosity with the experimental sample in *a*. *c*, Lithification texture after dry compression of well-rounded quartz grains. Only a few grains remained intact—highly angular fragments and cryptocrystalline quartz powder originate during brittle failure. *d*, Thin sectioned natural quartzite indicating the role of purely mechanical phenomena, such as grain crushing, in the creation of lithification textures in natural sediments.

As a first step in the experimental investigation of lithification textures, brass pressure cells were constructed. A massive steel piston was used to create a confining pressure in brass rings (20 mm high, with walls 2 mm thick). A first series of experiments, consisting of the compression of various dry granular sediments, revealed that a considerable degree of grain crushing took place. With granular material, shear stresses at grain contacts predominate during compression, initiating brittle failure. Compression of only a few grains in excess liquid medium, creates a hydrostatic pressure, without markedly affecting the grains. Thus, by varying the initial quantity of pore liquid mixed with the dry sample, control over pore pressure can be obtained.

The pore medium used in the experiments consisted of a liquid plastic. Minerals are unlikely to dissolve in, or react chemically with, this, and the plastic acts at the same time as the embedding medium, allowing thin sectioning of the compressed sample. After mixing a small quantity of dry granular sediment (for example, quartz sand, carbonate bioclasts, calcite crystals, fragments of feldspar, garnet, topaz, beryl) with different amounts of the liquid plastic, compression took place, reaching maximum loading in minutes. Samples were compressed with a load of 7,000 kg, creating confining pressure of some $1,000 \text{ kg cm}^{-2}$. This value of 1 kbar corresponds to a depth of burial of some 4.7 km when using an average density of the sediment cover of 2.7 g cm^{-3} . No means of artificial heating was used; therefore, the textural changes are caused by mechanical processes only (see also ref. 6). After hardening of the plastic, the brass ring was partially removed using a rotary cutter. After thin sectioning, samples were analysed with a polarising microscope.

Examination of numerous samples that were subjected to laboratory compaction reveals the existence of two major mechanisms responsible for the creation of lithification textures: plastic deformation and grain crushing. Two, more or less characteristic examples of the newly created lithification textures were selected (Fig. 1*a* and *b*). Rapid compression of a quantity of calcium carbonate bioclasts (clam shells, echinoid fragments, coralline algae, and encrusting algae) to $1,000 \text{ kg cm}^{-2}$ not only leads to the total disappearance of porosity (and permeability), but also causes the creation of a multitude of indentation contacts resulting from the plastic deformation of the grain contacts

(Fig. 1). Although a certain degree of grain crushing (brittle failure) takes place during the compression of the bioclasts, almost all the grains still show clear evidence of their original texture. The nature of grain contacts formed should be compared with thin-sectioned natural samples to evaluate the possible role of plastic deformation in the creation of lithification textures. As can be seen in Fig. 1*b*, a thin section prepared from a natural bioclast grainstone, indentation grain contacts and the total absence of porosity are also characteristics of certain natural limestones.

The second mechanism responsible for the creation of lithification textures is observed on dry compression of a well rounded quartz sand at a confining pressure of $1,000 \text{ kg cm}^{-2}$. Many of the well rounded grains break into

angular fragments and even into smaller fragments closely resembling cryptocrystalline quartz (Fig. 1c). Comparison with a natural quartzite sample (Fig. 1d) reveals once again the value of the experimental creation of lithification textures: the microfabric formed closely resembles that of the sample obtained by laboratory compression. The experiments reveal the existence of mechanisms other than the geochemical reactions postulated under the concept of "diagenesis".

In conclusion, the significance of the experimental approach in the analysis of lithification textures seems to have been established, adding an extra dimension to existing methods of geological high-pressure research.

Stable carbon and oxygen isotope ratios of groundwaters from the Chalk and Lincolnshire Limestone

SAMPLES of groundwater have been collected from the Chalk of the London Basin and the Lincolnshire Limestone in eastern England to determine the radiocarbon and the $^{13}\text{C}/^{12}\text{C}$ ratio in the dissolved carbonate species, and the $^{18}\text{O}/^{16}\text{O}$ and D/H ratios of the water. The results will be published more fully elsewhere, but here we report preliminary findings of the $^{13}\text{C}/^{12}\text{C}$ and $^{18}\text{O}/^{16}\text{O}$ ratios and their implications.

In the London Basin the $\delta^{13}\text{C}$ changes from about -13‰ in and near the outcrop of the Chalk to values less negative than -1‰ about 8 km from the outcrop; the least negative value recorded was -0.5‰ (Fig. 1). Similarly, in the Lincolnshire Limestone, values became less negative in the direction of groundwater flow, reaching -2‰ some 15 km

from the outcrop. These low negative values are unusual. They approach those for the carbon of the London Chalk and Lincolnshire Limestone matrices of $+2.4\text{‰}$.

The radiocarbon content of carbonate species dissolved in groundwater is a function of: (1) the time that has elapsed since the carbonate was in contact with a source of modern carbon, and (2) reactions between the aquifer and the dissolved carbonate species.

The latter have an important bearing on the interpretation of the radiocarbon results. The $^{13}\text{C}/^{12}\text{C}$ ratio is essential for the evaluation of the magnitude of reactions, other than radioactive decay, which may change the ^{14}C content of the groundwater¹. The use of the $^{13}\text{C}/^{12}\text{C}$ ratio in the interpretation of ^{14}C data is based on the fact that the principal sources of the carbonate species in water give different values for the ratio. Thus, either the contribution of different species to the measured ^{14}C in the sample can be estimated, or the measurements can assist in the understanding of the groundwater chemistry. Interpretation of the carbonate chemistry is necessary to assess the correction factor that must be applied to the radiocarbon content because of dilution by non-radioactive carbon.

Although changes in the carbonate chemistry of groundwater in the London Chalk and Lincolnshire Limestone do take place in a down-gradient direction (because of ion exchange, carbonate precipitation and sulphate reduction^{2–4}), these changes alone cannot account for the very small negative values measured. The bicarbonate concentration of the water only increases from about 270 mg l^{-1} in the Chalk outcrop to about 380 mg l^{-1} in the centre of the London Basin (a distance of some 15 km). Similarly, in the Lincolnshire Limestone the increase is only from 270 mg l^{-1} in the outcrop zone to about 460 mg l^{-1} down gradient.

In view of this, the low negative values seem to be due to either isotopic exchange between the carbonate in the aquifer and bicarbonate in the water or continuous precipitation and solution of carbonate as the water flows slowly between the individual constituent particles of the limestone matrix. This view is supported by the fine-grained nature of the aquifers, particularly the Chalk, and the consequent large surface area that exists in contact with the water. Isotopic exchange is, however, a very slow process and is unlikely to have had a significant effect over the timespan during which radiocarbon dating can be applied¹. Therefore continuous precipitation and solution is favoured as the process responsible for the low negative $\delta^{13}\text{C}$ values.

On the basis of this interpretation, the radiocarbon analyses have been corrected to derive an age for the water

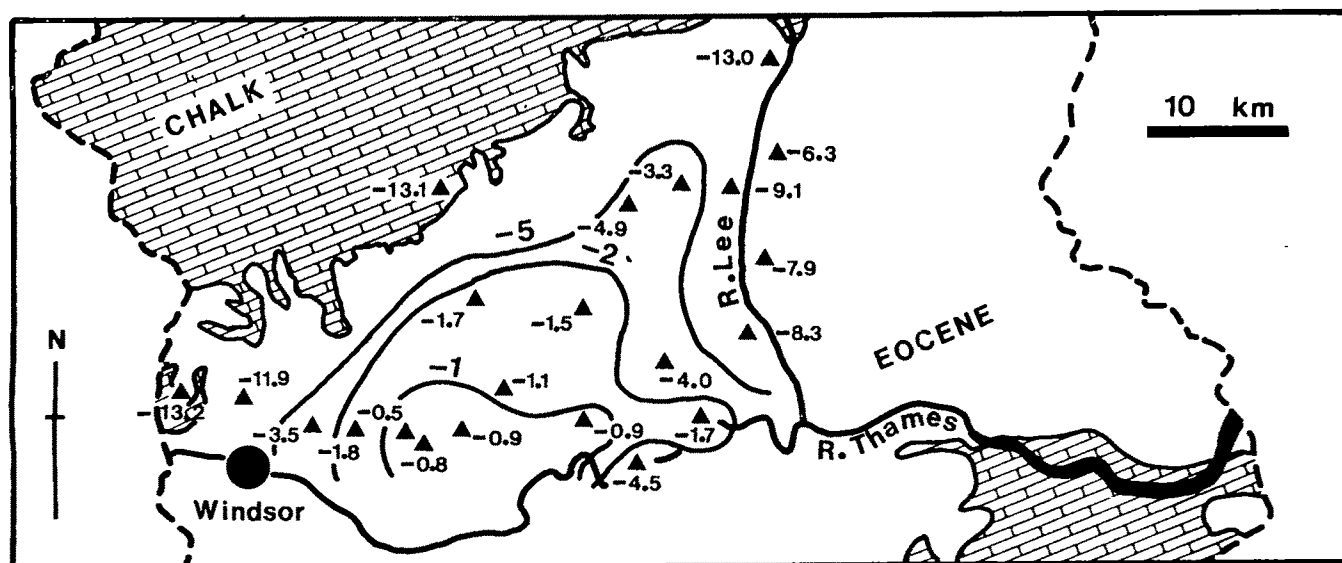

Fig. 1 $\delta^{13}\text{C}$ values (parts per 10^3) for groundwater in the Chalk in part of the London Basin.

in the centre of the London Basin and in the eastern part of the Lincolnshire Limestone in excess of 25,000 yr. The correction assumes that in fine-grained carbonate aquifers, the volume of the rock greatly exceeds the carbonate precipitate, and re-solution of previously precipitated carbonate is insignificant.

An age greater than 25,000 yr implies that the water originated in rainfall during the Pleistocene. The ratios of the stable isotopes $^{18}\text{O}/^{16}\text{O}$ and D/H in this Pleistocene water are in the proportions found in present-day normal meteoric water¹. The range of $\delta^{18}\text{O}$ in the Pleistocene water in the centre of the London Basin is from -7.7% to -7.9% whereas in modern water from the periphery of the Basin, the range is -7.1% to -7.2% . This suggests that either the temperatures at the time of recharge were less than one degree cooler than today², or the weather patterns producing the recharging rainfall differed from those operating now. A possible explanation is that recharge occurred during relatively mild climatic phases of the Weichselian glaciation and that it was limited to summer periods because frozen ground prevented recharge in the winter.

Processing structure of sentence perception

To extract meaning from a sentence, the listener must combine information from several levels of linguistic analysis. Psycholinguistic research¹ has documented a range of processing levels from the phonetic to the semantic, but has not explored the central problem of specifying the interactions between these levels. We have examined three fundamental questions about the processing structure of sentence perception. When, during sentence processing, does information at different levels become available to the listener; what is the time-course of the interactions between these levels; and what is the direction of information flow between them?

We used three speech monitoring tasks, in which the subject listens to a sentence and makes a timed response when he hears the target word. Identical monitoring, in which the subject knows in advance exactly which word to listen for, provides a baseline for assessing performance in the other two tasks. In rhyme monitoring, where the subject listens for a word that rhymes with the cue word given in advance, his response need only require a phonetic analysis of the target. But in category monitoring, where the target is a word belonging to a taxonomic category specified in advance, the response depends on a semantic analysis of the target. By placing these target words at different serial positions in the test sentences, we can measure the time course of different levels of processing.

The three monitoring tasks were also co-varied with three

types of prose context—normal prose (NP), syntactic prose (SP), and random word order (RWO). If monitoring in an NP context is facilitated by the presence of sentence-level syntactic and semantic information, then response latencies will increase when there is no semantic interpretation available (in SP), and when syntactic information is also unavailable (in RWO).

Our earlier research^{2,3} leads us to propose an interactive parallel model of sentence processing, in which, from the first word of a normal sentence, the analysis of the input is conducted at all available processing levels. In particular, the information available at any one level of analysis can constrain and facilitate decisions at any other level, so that the continuing phonetic and lexical processing of each word is directly influenced by its current syntactic and semantic context³. As we will make clear in discussing the results, the predictions of this approach will contrast with those of serial theories, which assume varying degrees of delay before information at any one level of analysis can interact with information at any higher level^{1,4}.

The experiment, in summary, combines three monitoring tasks, three prose contexts, and nine word positions. Eighty-one target words were distributed equally across the second to the tenth word positions in the second sentence of 81 pairs of NP sentences. The same target words in the same word positions were also embedded in 81 SP and 81 RWO sentences. These materials were then assigned to nine versions, such that each of 45 subjects heard each of

Fig. 1 Overall monitoring response latencies (with standard errors indicated) for each monitoring by context condition. Each cell represents the mean of 405 observations, counterbalanced so that each subject, target word and word position contributed equally to each of the nine means. The SP sentences were constructed by replacing pseudo-randomly all content words in the NP sentences, except the target words, with new words of the same form-class and frequency. The RWO sentences were constructed by scrambling the word order of the SP sentences, keeping the serial position of the target word constant. The same target words occurred in each monitoring condition, but with different cue words given in advance. Thus, if the target word was 'cat', the cue word for identical monitoring was also 'cat', while in rhyme monitoring it was 'pat', and in category monitoring the category name 'animal'. ●, NP; ○, SP; ▲, RWO.

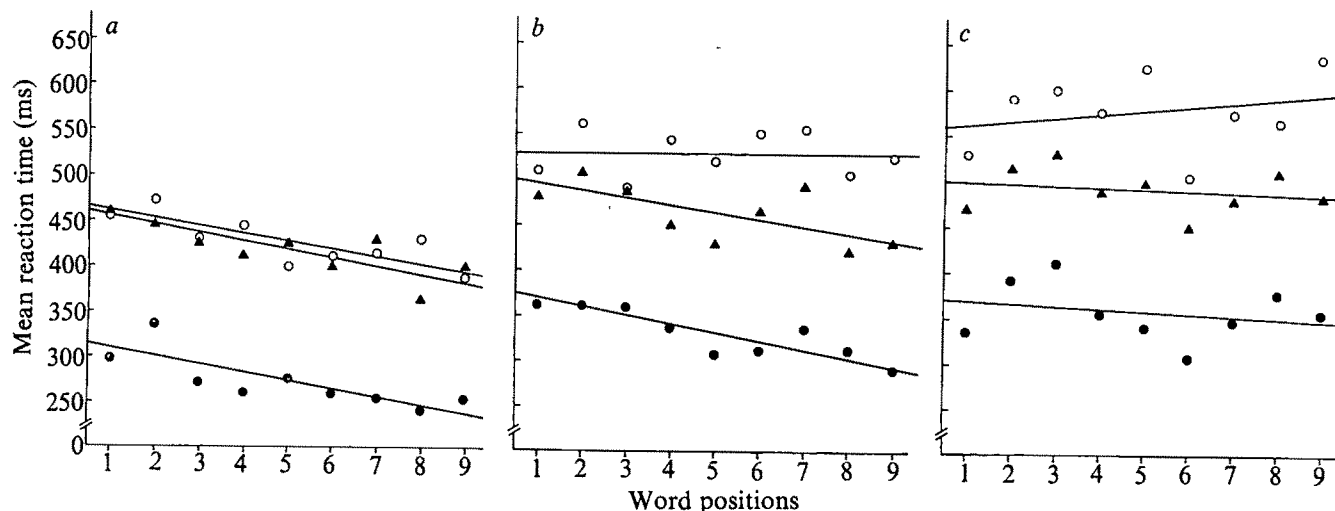

Fig. 2 Monitoring response latencies in each monitoring by context condition as a function of the word-position of the target word. Each point is the mean of 45 observations. Best-fitting least squares regression lines are drawn for each condition. Word-position 1 is the second word in the test sentence. *a*, NP; *b*, SP; *c*, RWO; ○, category; ▲, rhyme; ●, identical.

the 81 target words in one of the nine combinations of context by monitoring conditions.

The overall results are summarised in Fig. 1. Min F^1 values were computed⁵, using the untransformed raw data, with missing observations (less than 2%) replaced. The main effects of monitoring and of context, and the interaction between them, were significant ($P < 0.001$). Each of the means differed significantly from all other means ($P < 0.01$), with the exception of NP rhyme and category monitoring.

Monitoring latencies are faster in all NP conditions than in SP or RWO, and SP monitoring is similarly superior to RWO. This is predicted by the interactive parallel model, in which both semantic and syntactic information interact directly with continuing lower level decisions. On a serial model, lower level analyses are performed first, before being integrated with higher level information. Thus there should be no latency differences between contexts when the monitoring response could be based just on lower-level information—as in rhyme monitoring.

In addition, there are no differences between rhyme and category monitoring in an NP context, but large differences in SP and RWO. According to an interactive parallel model, semantically based decisions in NP can be just as fast as phonetically or lexically based decisions, since the listener develops a unified multi-level representation of the material as he hears it, and the higher and lower level attributes of this representation are equally accessible for making the monitoring response.

In contrast, any serial model has to predict longer latencies for category monitoring, since the defining characteristic of a serial model is that higher level decisions must, to some measurable extent, await lower level decisions. It should be noted that category monitoring in SP and RWO is much slower than rhyme monitoring, showing that the similarity between them in NP depends on the continuing semantic interpretation at the sentential level.

Effects of word position (Fig. 2) are found only in the conditions where hearing more of the sentence gives the subject additional information at the higher levels of analysis relevant to his responses. Latencies decrease as a linear function of word position in all NP monitoring tasks and in SP identical monitoring, with a weaker effect in SP rhyme. In particular, the goodness of fit and the slopes of the linear regression lines are remarkably similar for these major effects (Table 1).

Thus the advantage of NP over SP in identical monitoring is the same at all word positions. Similarly, within NP, the dissociation between identical and rhyme or category

Table 1 Regression of context by monitoring latencies on word position

Monitoring task	Prose context		
	NP	SP	RWO
Identical	$r = -0.78^*$ $b = -8.20$	-0.87^* -8.62	-0.21 -2.35
Rhyme	$r = -0.79^*$ $b = -8.18$	-0.64^\dagger -7.27	-0.19 -1.68
Category	$r = -0.78^*$ $b = -7.67$	-0.005 -0.05	$+0.25$ $+3.78$

r , Pearson product-moment correlation coefficient; b , slope of linear regression line in ms.

* $P < 0.001$.

† $P < 0.05$.

monitoring is the same over word positions. This bears out the interactive parallel claim that analyses at all levels are initiated from the first word in a sentence. Although a serial model could predict differential decreases in latency for the later word positions, the differences between conditions should be minimal earlier in the sentence.

The data, therefore, consistently support an interactive parallel model. On the assumption that the monitoring task reflects the processes involved in ordinary listening, we conclude that a representation of the input at all available levels is initiated immediately in sentence processing, such that bi-directional and reciprocal interactions between these levels also begin very early in processing. The processing of spoken language, whether by humans or computers^{6,7}, may only be feasible when all available constraints, at whatever levels of analysis, are brought together during processing to limit the size of the search space within which the interpretation of the input is being established.

Determination of perspective reversals

MANY outline drawings of geometrical objects go through apparent reversals of perspective during prolonged viewing, and no adequate explanation for this is known¹. A classical explanation is that satiation or fatigue of the neural process which mediates the perception of one perspective leads to a replacement of the process by another one which has not been recently active²⁻⁴. I tested the satiation theory by studying whether the apparent reversals of perspective can be determined by adaptation to an unambiguous perspective seen in a stereogram or in a three-dimensional object. Adaptation blocked temporarily the appearance of the corresponding perspective in a reversible perspective figure.

Fig. 1 Determination of perspective reversals through disparity specific adaptation. *A* and *B*, Adaptation stereograms with opposite disparities. *T*, Test stereogram without disparity. If reader stereoscopically fuses the test pair, an alternating perspective of the staircase is seen. Pairs *A* and *B* if properly fused produce a stereoisimage which does not alternate in perspective. Adapt to *A* for a minute and observe then *T*: the apparent perspective of the test image now is opposite to that observed in *A*. Repeat the same by adaptation to *B* and notice that after adaptation to *A* or *B* the perspective of *T* is always opposite to the one observed in the adaptation figure.

The Schröder staircase served as the stimulus figure. The adaptation and test stereograms are shown in Fig. 1. There was no disparity in the test stereogram *T*. So its apparent perspective alternated: the staircase could be seen either from above (case *A*) or from below (case *B*). The adaptation stereograms (*A* and *B*) contained 3 mm of horizontal disparity so that pair *A* formed a stereoisimage in which the staircase was seen from above and pair *B* formed an image in which the staircase was seen from below.

The stereograms were projected on to a screen with the aid of two timer-controlled projectors behind the screen. The subject viewed the screen at a distance of 57 cm, with his head held against a chin rest. A black divider extended

from the subject's forehead to the screen; hence, each eye saw only one half of the tangent screen. One half of the stereogram was shown to each eye. Prisms and lenses fitted into a spectacle frame corrected the retinal images of the figures so that a good fused image was formed. Subjects who were not able to form a stable stereoisimage were rejected.

Black fixation crosses, one for each eye, were continuously present on the screen. With adequate fusion, the subject saw one luminous staircase figure and one black fixation cross in its centre. The fixation crosses were 6.4 cm apart and the size of the fused figure was 5.2 × 5.2 cm. The luminance of the stimulus lines was about 500 cd m⁻² and that of the background was 50 cd m⁻².

Four adaptation series were run, each consisting of ten trials. Each trial consisted of four events: (1) 5-s fixation to the adaptation figure, (2) a half second pause during which fixation was held, (3) one second fixation to the test figure, and (4) 10-s pause. The subject reported verbally or by means of a switch the apparent orientation of the staircase during its presentation. The test stimulus itself was used as the adaptation stimulus in the first and last adaptation series (controls 1 and 2). In the middle series, pairs *A* and *B* were used as adaptation stereograms, in alternating orders for different subjects.

Figure 2 shows the results for 18 subjects. When a stereogram without disparity served as the adaptation stimulus, 29.4% of all reports in control 1 and 33.3% in control 2 were case *B* reports. After adaptation to type *B* stereogram the average number of *B* reports fell to 4.6% and after adaptation to type *A* stereogram the number rose to 61.1%. Thus, it is clear that adaptation to a stimulus containing disparity led to a considerable decrease of reports of similar perspective in the test stimulus. The effect became stronger as a function of repeated adaptation. At the end of the ten-trial series 83% of subjects reported case *B* in the test figure after adaptation to *A* and no subject reported *B* after adaptation to *B*. Thus, 50 s of distributed adaptation time led to an almost complete determination of the perspective perceived in the neutral test figure.

The decay time of the adaptation effect was determined for 6 subjects by recording the apparent perspective of the test stimulus continuously. After a 1-min adaptation to a stereogram with disparity the average frequency of *B* reports returned to the unadapted level in about 20 s.

In some experiments, a three-dimensional Schröder staircase model was used as the adaptation stimulus. The

Fig. 2 Development of the disparity specific aftereffect during repeated testing after various forms of adaptation. Ordinate shows the percentage of subjects ($N = 18$) who saw perspective alternative *B* in the test figure which could be seen either as alternative *A* or alternative *B* during its 1-s presentation. Each test trial was preceded by a 5-s adaptation period. In control series the adaptation stimulus was the same as the test stimulus. In adaptation *B* the disparity of the adaptation stimulus evoked a perspective view of type *B*. Adaptation stimulus *A* evoked perspective *A*, respectively.

model was made of plastics and the edges of the model were black; the model produced projections like the ones shown in Fig. 1. Adaptation to the model prevented the visibility of the adapted perspective in a corresponding two-dimensional projection of the model. Thus, adaptation to a three-dimensional model produced the same result as adaptation to a stereogram.

These aftereffects are similar to other aftereffects in the third dimension⁵⁻⁷ in the sense that they are generated through adaptation to binocular disparity. They differ in the test stimulus in which the effects are observed. In the usual disparity-specific aftereffects the perceived depth of the test stimulus depends on actual disparity and the effect of adaptation can easily be understood through a change of perceived disparity. The present aftereffects are observed in the perspective of an object which is represented by a drawing; the apparent depth of the depicted object is not conveyed by means of disparity cues. The effect of adaptation in this case is paradoxical because adaptation to disparity affects a perceptual property which is not presented through disparity.

The results support the satiation theory of perspective reversals because they show that forced adaptation to one perspective view decreases the likelihood of continued perception of the same perspective. The role of binocular disparity in the adaptation effect is puzzling, however. It is evident that the satiation theory is not strictly testable as long as the neural processes mediating the impression of perspective in an object presented by a two-dimensional outline drawing remain unknown. The present results indicate that satiation taking place in disparity-specific neural mechanisms⁸⁻⁹ would be sufficient for inducing perspective reversals. The state of disparity-specific neural mechanisms seems to be one possible determinant of apparent perspective seen in drawings but the results do not imply that the perspective reversals ordinarily seen are caused by adaptation of these neurones.

Is the aestivating lungfish the first vertebrate with suctional breathing?

THE current view is that ventilation of the lungs by aspiratory, negative-pressure inhalation probably occurred in the earliest, now extinct amphibians¹. But no aspiration breathing has been demonstrated in extant air-breathing vertebrates below reptiles, which use freely movable ribs and specialised muscles for this purpose. We report experiments showing that the aestivating lungfish relies on suctional breathing.

When the lungfish is in water the lung is ventilated by essentially aquatic breathing movements involving a buccal, positive-pressure swallowing of air, whereas expiration is largely effected by passive compression of the lung from the external water as the head is raised to the surface and the glottis opened². This basic mechanism of inspiration was passed on in only slightly modified form to the lunged amphibians. When the lungfish aestivates, however, in a soil-encased cocoon³, conditions for breathing are quite different. Air breathing alone can support its aerobic metabolism

Fig. 1 Schematic representation of aestivating lungfish showing position of pneumotachograph tube and cannula for pressure measurements. The fish is covered by a cocoon (solid outline) and embedded in soil.

when, at the start of aestivation, the lungfish becomes enveloped by a hardened mucous secretion. This cocoon covers the entire surface and even enters the mouth to form a hollow, non-collapsible breathing tube connecting the bucco-pharyngeal cavity with the air channel in the soil leading to the outside air. This prevents the movements of the buccal floor, such as practised in the free swimming lungfish. More importantly, it prevents complete closure of the mouth and thus compels the animal to suspend positive-pressure buccal pumping for filling its lung.

The lungfish, *Protopterus amphibius*, Trewavas, used in our study were naturally aestivating and had been dug out of a dried up lake bed near Malindi, Kenya, 2 yr previously. Eight fish encased in the same soil in which they had entered aestivation, were transported by air to Aarhus where they were kept at 25 °C for 18 months before our study.

The breathing pattern of the fish was recorded continuously by pneumotachography (Statham-Godart) and pressure measurements (Statham) (Fig. 1). In addition, the soil surrounding some of the aestivating lungfish was removed carefully to expose the head and floor of the buccal cavity for visual observation of movements correlated with breathing. In one specimen a catheter was passed through the hollow breathing tube and into the buccal cavity to record pressure. Finally, one aestivating specimen was subjected to X-ray examination to reveal the size of the lungs and airways.

Figure 2 shows that normal breathing was periodic with a series of ventilatory movements alternating with apnoeic periods, which lasted from a few minutes to several hours. A ventilatory period always started with an inspiration. Inspiration was a two-phasic process—an initial phase of relatively rapid inflow (0.2 ml s^{-1}) ran, after a period of no air flow, into a second inspiratory phase when volume flow was less (0.1 ml s^{-1}) but lasted longer (Fig. 2). The longer lasting phase contributed most to the inspiratory volume, which typically totalled about 0.3 ml. The inspiratory phases lasted about 70% of the entire breathing cycle. The two phases of inspiration were attended by two cycles of negative (subambient) pressure recorded in front of the breathing tube. The second inspiratory phase ran directly into a single-phase expiration which was the most forceful of the breathing movements, resulting in air flows exceeding 1 ml s^{-1} .

Fig. 2 Tracings showing: a, rate of inspired (upward deflection) and expired air flow, \dot{V} ; b, inspired and expired volumes V_{I+E} ; c, inspired volume, V_I ; d, pressure at entrance of breathing tube, P .

A positive pressure (0.3 mm H₂O) more than twice the value of the negative pressure associated with inspiration correlated with the rapid expiration lasting about 10% of the breath cycle. The expired volume matched the combined volumes of inspiration in phases one and two. Thus both volumes inspired enter the lung and must do so as a result of suctional inhalation.

Pressure pulses recorded in the buccal cavity closely resembled those recorded in the air space in front of the breathing tube (Fig. 1). This is further evidence that air enters the lung by suctional attraction. If the first volume of air entering the lungfish had been positioned in the mouth for a second phase positive-pressure force filling of the lung, two positive-pressure phases, one attending the buccal force pump, the other the expiratory phase, should have been recorded from the mouth catheter. Further, if a positive buccal pressure filled the lung, no air flow should have been recorded through the pneumotach. As the recordings show, all pressure pulses were associated with air flow through the head of the pneumotach. Visual observation of the buccal floor during breathing showed no movements suggesting filling or emptying of the buccal cavity.

The X-ray study similarly showed a rather narrow air channel extending from the breathing tube through the buccopharynx to the lung. A buccal force filling the lung is thus also ruled out on this basis. The X rays revealed a surprisingly large lung shadow. A large lung volume in the aestivating lungfish was also suggested by the observation⁴ that a carefully excavated aestivating lungfish would float high when returned to water. Conversely, the breathing volumes recorded presently from aestivating lungfish are much smaller than those earlier estimated indirectly from non-aestivating fish⁵.

These data tend to support the hypothesis that suctional breathing probably evolved first in aestivating lungfishes. The mechanics of the breathing process and the activity of the associated muscles and skeletal parts are unknown.

Chemically-mediated host selection in a parasitic mite

MITES parasitise a broad spectrum of metazoans—molluscs, arthropods and vertebrates, including man. They transmit various pathogens to these hosts, and may cause severe medical and economic damage^{1,2}. Host preferences are commonly restricted to one or a few species³, and parasitism may result in profound ecological or biological effects, for example, the regulation of clutch size in birds⁴. Such effects have prompted some investigators to suggest the use of acarine parasites as natural control agents^{5,6}. In spite of all these factors, little is known about how mites select their hosts. We studied host discrimination in a typical acarine parasite, *Proctolaelaps nauphoetae* (Womersley)^{7,8}, and report that it uses a chemical sense to guide it to its only host, the cockroach *Nauphoeta cinerea* (Olivier).

Studies of other arthropod parasites (Hymenoptera) view host discrimination as three consecutive processes⁹⁻¹²: finding the host's environment, selecting an appropriate host, and accepting or parasitising this choice. Acarine parasitism seems to fit this pattern. In this report we focus on the mechanisms by which *P. nauphoetae* selects its host.

Mites use their first pair of legs as chemosensory organs^{1,2}. Ablation of these appendages renders *P. nauphoetae* incapable of finding a host¹³. Therefore we examined the attractiveness of potential chemical stimuli in two-choice preference tests. Material was applied to 7-mm paper disks and exposed to 15–25 mites in a specially designed chamber¹³. Each pair of stimuli in a test was matched in shape, size, texture, solvent and treatment so that the only difference between them was the material being tested. Mite distributions were determined after 3 h, and each experiment was replicated five or more times. The null hypothesis in all experiments was that mites would be equally distributed between the two choices. The G statistic was used to test the homogeneity of replicates and their goodness-of-fit to the null hypothesis. Probabilities cited below refer to the goodness-of-fit. Control experiments showed that mite movements were not influenced by chamber design ($P > 0.9$) or the presence of other mites ($P > 0.9$). Mites avoided white light ($P < 0.001$) but not red ($P > 0.9$); therefore all experiments were conducted under red illumination at constant temperature (27 °C) and humidity (50%). More than 12,000 mites were tested.

N. cinerea is a gregarious cockroach, forming colonies of several hundred individuals which live in close contact with one another and their own detritus¹⁴. As a result materials from faeces, expectorants, dead individuals and rotting debris are carried by each cockroach and could be used by mites as cues. We collected faeces from nine species representative of all phylogenetic lines of cockroaches¹⁵. Mites were attracted to all these ($P < 0.05$) except one, *Eurycotis floridana* (Walker), known to produce a strongly repellent compound¹⁶. Faeces from a laboratory rat were also attractive ($P < 0.01$), as was skatole ($P < 0.03$). These results suggest that mites are generally attracted to faeces, but do not rule out the possibility that additional attractive materials occur in host excrement. This was shown not to be the case: in a choice between host and non-host faeces, mites were equally attracted to both ($P > 0.95$).

In addition to faeces, mites showed a nonspecific attraction to legs excised from several cockroach species ($P < 0.01$), cockroach detritus ($P < 0.01$), and two compounds occurring in rotting organic material, putrescine and cadaverine ($P < 0.03$). These results suggest that *P.*

Fig. 1 Separation of nauphoetamine, a host-specific cue. Map of the components from cockroach extracts indicated by ninhydrin after high voltage paper electrophoresis (2–1/2 kV, 30 min, pH 6). Extracts were applied in equivalent concentrations on the dotted line after treatment with gel filtration. Mite responses to these components are indicated. Abbreviations: HOST, *Nauphoeta cinerea* (Olivier); LEU, *Leucophaea maderae* (Fab.); BYR, *Byrsotria fumigata* (Guérin); CRAN, *Blaberus craniifer* Burmeister; DISC, *B. discoidalis* Serville; AUS, *Periplaneta australasiae* (Fab.).

nauphoetae can recognise the proximity of potential hosts—a cockroach colony. To test this hypothesis, we isolated several hosts from their colony for 3 weeks, then tested them against colony-dwelling individuals. These mites categorically preferred the latter ($P < 0.001$); conversely, they were attracted to (but did not parasitise) a non-host cockroach (*Periplaneta australasiae* [Fab.]) that was permitted to live in a host colony for 3 weeks ($P < 0.01$).

P. nauphoetae showed a selective preference for cockroach excretants rather than faeces and detritus. They were attracted by material produced by representative species in the host's family, Blaberidae ($P < 0.05$), but not by species in other families ($P > 0.9$). In addition, host excretants were more attractive than host faeces ($P < 0.001$). These results suggest that excretants, spread over a cockroach's body by grooming, could inform parasites that a potentially suitable host was near. Supporting this hypothesis is the result that 45 of 54 mites, observed while searching for a host, made a discrete and consistent change in their searching pattern as they neared a host.

Clean filter paper placed in a cockroach colony for several weeks became impregnated with material that strongly attracted *P. nauphoetae* ($P < 0.99$). In addition, their searching behaviour was essentially the same in the presence of either this paper or a live cockroach. Extraction of this paper with acetone, methylene chloride, ether, petroleum ether, methanol and ethyl alcohol failed to remove attractive material ($P > 0.9$). Aqueous buffers at a pH greater than 7 completely removed attractant ($P < 0.005$), and boiling destroyed its activity ($P > 0.99$).

The active extract was concentrated by lyophilisation and applied to a column of Sephadex G-50 calibrated for

polysaccharides¹⁷. Column effluents were pooled into three molecular weight fractions, concentrated, and tested for their attractiveness. Only one fraction (1,500–6,500 daltons) attracted these mites ($P < 0.005$). This active fraction was lyophilised, redissolved in pyridine buffer, pH 6, and electrophoresed on paper at 2.5 kV for 30 min. Half of this electrophoretogram was stained with ninhydrin for amines, *p*-anisidine for ketoses¹⁸, or Morgan–Elson reagents for hexosamines¹⁹. Ninhydrin indicated 10 cationic bands (Fig. 1). Of these, three bands—VIII, IX, and X—also reacted to the hexosamine test; there was no reaction to the ketose test. The other half of the electrophoretogram was cut into 0.25-cm² pieces and assayed in preference tests. Only band VII strongly attracted *P. nauphoetae* ($P < 0.005$); two other bands (IX and X) may have been weakly attractive ($P = 0.15$). We have observed the band patterns in Fig. 1 in 23 runs using five different extracts.

To determine whether the attractant isolated by electrophoresis is unique to the host, we collected material from five non-host species representing the major phylogenetic lines of cockroaches. These materials were extracted, gel filtered and electrophoresed exactly as was the host material. Electrophoretograms were marked with host extract, stained with ninhydrin, and material from non-host species occurring around band VII was offered to mites (Fig. 1). None of this material was attractive ($P > 0.9$), including one band with the same mobility as the marker; material from two species was slightly repellent. From these experiments we conclude that band VII from *N. cinerea* contains a host-specific attractant.

Further chemical analysis of band VII is planned. Preliminary results by ion exchange chromatography, thin-

layer chromatography, spectroscopy and spot testing suggest that it is a glycosaminoglycan, a poly-amino sugar. The only definite conclusion is, however, that band VII is a polar macromolecule which contains a primary or secondary amine and has a molecular weight between 1,500 and 6,500. Considering these facts, and the source of the material, we propose the name nauphoetamine.

Three chemically mediated levels of discrimination were used by these parasites. The probable relationship between mite behaviour and the process of host discrimination is shown diagrammatically in Fig. 2. The first level is host proximity for which faecal odour and colony detritus seem to be cues. Perception of these cues initiates a random, undirected search (foraging). In time, this activity brings it close enough to a cockroach (or other animal), to determine if it is a potential host—the second level of discrimination. Appropriate chemical cues, for example, cockroach expectorants, result in a direct orientation. In the final approach the third level of discrimination occurs: the parasite can determine through perception of nauphoetamine whether the cockroach is the correct species. If not, it resumes foraging or engages in some other activity. If so, it moves to the abdomen, grooms its legs, and attempts to find an unoccupied feeding site^{7,8}. If unsuccessful, the mite abandons the cockroach and continues to forage. If a feeding site is found, however, the process of host discrimination is consummated by attachment which may be followed by feeding and eventual reproduction.

The Clayton Foundation at the University of Texas, and G Barrie Kitto provided instrumentation and assistance for parts of this study. V. Dethier and A. Gelperin contributed useful suggestions concerning the manuscript.

Cell within a cell or a circulating cell pair

I WISH to report that one of the coelomocytes of *Phascolosoma agassizii* Keferstein, 1866¹ (collected from Arroyo de Frioles State Beach, California) which was previously considered to be one granulocyte is seen, under the electron microscope, to consist of two separate cells in a unique relationship.

The most unusual and distinctive feature of this cell pair is that there are two structurally separate cells, one within the other. In more than 100 electron micrographs of such cell pairs chosen at random, and in five pairs serially sectioned, no cell junctions, cytoplasmic bridges or points of fusion between the two cells were found.

The external cell (E) is a complete cell containing a nucleus (NE) and a scant rim of cytoplasm which surrounds the internal cell (Fig. 1). The cytoplasm of the external cell (Fig. 2) contains a Golgi complex (Gc), mitochondria, smooth and rough endoplasmic reticulum, free ribosomes and small electron-dense granules, as well as larger granules which are similar in appearance to vertebrate lipofuscin granules (Lf). At high magnification, small fenestrations 0.018 μ m wide are occasionally distinguishable along the external plasma membrane (arrows). This may be an artefact resulting from the plane of sectioning of the irregular buffy-coated outer membrane.

The external cell is separated from the complete internal cell by an extracellular space averaging 0.07 μ m wide filled with a fibrillar reticulum (Fig. 2).

The cytoplasm of the enclosed cell is almost filled with large granules of various densities. The outer granule membranes are often lined with ribosomes (not visible in the fields shown). The nucleus of this cell (NI) is displaced to a site near the border of the external cell. The organelles—a Golgi complex, mitochondria (M), rough endoplasmic reticulum, free ribosomes, microtubules and glycogen (Figs 1 and 2)—are concentrated around the nucleus where new granules can often be seen forming from the Golgi complex.

I observed no granules being extruded from the cells or disruption of the granules during clotting of coelomic fluid. But during routine processing for electron microscopy, the

granules of the enclosed cell often disrupted, leaving the associated cell, reticulum fibres and enclosed cytoplasmic membrane. No cells were observed in mitosis and the GAC (granulocyte with its associated cell) was non-phagocytic.

Of the four morphologically distinguishable cell types found in the coelomic fluid of *P. agassizii* (omitting gametes) the cell within a cell was the least common. For every three ciliated urns, 30 granulocytes and 566 haemocytes, there was only one GAC (counts taken from 25 pooled blood samples, four worms each). The GAC ranged in size from $26\mu\text{m} \times 15\mu\text{m}$ to twice this length and width. In preparations of whole cells stained with Wright's blood stain two nuclei were seen per GAC. The nuclei were observed in all possible positions relative to each other, from close together to opposite poles (Figs 1 (inset) and 2).

In paraffin sections, 4–6 μm , the granules in the enclosed cell exhibited two staining reactions with periodic acid-Schiff (PAS), Giemsa and trichrome stains². They were either PAS positive or negative; PAS-negative granules stained orange with PAS-orange G. With Giemsa the granules stained acidophilic or basophilic, and with trichrome, they stained red or green. One cell sometimes exhibited granules with both staining properties although homogeneously stained granules were the most common form. No histochemical stain differentiated the internal granulocyte from its external associated cell.

When 0.5- μm sections embedded in Araldite and stained with Toluidine blue were viewed by light microscopy, the external associated cell was not visible unless some internal granules had been disrupted. In most GACs, the granules of the internal cell obscured all other cytoplasmic features (inset, Fig. 1).

In unfixed preparations of whole cells, the GAC was reactive for both lipase³ and alkaline phosphatase⁴. Light microscopy indicated that all large internal granules were positive for lipase whereas the alkaline phosphatase reaction was random, often appearing more prominent around the periphery.

A circulating cell pair is an unusual finding. There is no report in the literature on invertebrates. Emperipolesis—cells within cells—has been reported in tumour cells⁵ of vertebrates and as a transitory state for migrating lymphocytes passing through the endothelial cells of post-capillary venules in lymph nodes⁶.

A diverse population of granulocytes has been observed

Fig. 1 Electron micrograph of a typical GAC. The cytoplasm of the inner cell, the granulocyte, is packed with dense granules. The associated cell is composed of a nucleus with scant cytoplasm completely surrounding the granulocyte. E, external cell; NE, nucleus of external cell; I, internal cell; Gc, Golgi complex; NI, nucleus of internal cell. —, Fenestration of external plasma membrane. Inset, toluidine-blue-stained Araldite section of a typical GAC.

Fig. 2 Electron micrograph of the nuclear area of the GAC. Reticular fibrils can be seen separating the two cells. Lf, lipofusein granules; M, mitochondrion; F, fibrillar reticulum. Other labels as for Fig. 1.

in various sipunculid species^{7–11}. One group of granulocytes is described as multinucleate, larger with larger granules and differing in its acidophilic staining and non-phagocytic nature; but using electron microscopy it has been shown that in *P. agassizii* these are actually two associated cells. The different histochemical properties of this cell type and occasionally within a single cell with either the PAS, trichrome or Giemsa stain, could indicate different stages in packaging and condensation of a mucoprotein granule product. Variations in density revealed by electron microscopy, and the formation of new granules from the Golgi complex show a developmental sequence in the granule population. The purpose of the granules of the internal cell and the special conditions under which they might be released is not known. The granulocyte with associated cell could be a regulatory cell. The associated cell with the extracellular reticulum appears to be a physical support for the large internal granulocyte. Perhaps changes in the coelomic fluid cause changes in the external cell, resulting in lysis of the support structure and release of the internal cell's granules.

Superior growth of the right gonad in human fetuses

RIGHT and left mammalian gonads do not usually differ noticeably either in size or development, in contrast to the situation in birds, where ovarian development is usually confined to the left side¹. Nevertheless, when the differentiation of the gonads follows an abnormal course, lateral asymmetry becomes apparent also in mammals. In human hermaphrodites, who have a testis as well as an ovary, the testis is preferentially situated on the right and the ovary on the left side^{2–4}. This

Fig. 1 Difference in fresh weight, total protein and total DNA contents between the right and left gonads of 14 male and 9 female foetuses aged between 20 and 28 weeks (estimated from crown-rump lengths). Bars represent the sums of the differences between right and left gonads, divided by the mean gonadal value, expressed in %; vertical lines represent \pm s.e. After removal, the gonads were stored in 0.03 M phosphate buffer, pH 7.0 at -15°C . Before analysis, pairs of gonads were thawed out and trimmed of extragonadal material under a dissecting microscope. Trimmed gonads were blotted dry on filter-paper, weighed and ground in the above phosphate buffer using a loose glass-glass homogeniser. Samples of the ground material were assayed in duplicate for protein (using the procedure of Lowry *et al.*¹²) and for DNA (as described by Burton¹³). Bovine albumin (Sigma) and herring sperm DNA (Sigma) Type IV were used to calibrate the protein and DNA assays respectively.

finding is independent of the chromosome constitution^{3,4}. Also, certain gonadal tumours are known to be more frequent on the right side; this applies to dysgerminomas, which are seminoma-like tumours of the ovary⁵. The question thus arises whether mammalian gonads exhibit an inherent but undetected asymmetry between right and left sides. To answer this question, we have compared right and left gonads from therapeutically aborted human foetuses, using the criteria of fresh weight, total protein and total DNA contents.

Figure 1 shows that when the values for left gonads are subtracted from the corresponding values for right gonads, the difference is positive for all three criteria in both males and females. We can thus conclude that the right gonad is superior to the left in both protein and DNA contents, and thus, one can confidently assume, in cell number. This difference seems to be greater in females than males. The larger size of the right compared with the left ovary has previously been reported in adult British horseshoe bats of the genus *Rhinopholus*, in which the follicles of the left ovary fail to mature⁶.

An increased growth rate of the right mammalian gonad, at least during part of its development, could explain the greater risk of some gonadal tumours developing on the right compared with the left side. Moreover, the preferential situation of testes on the right and ovaries on the left side in patients with hermaphroditism²⁻⁴ may be accounted for simply by the asymmetrical growth of the two gonads in normal mammalian foetuses.

Foetal testes grow markedly faster than ovaries in rats⁷ and mice⁸. We have observed a similar effect in human foetuses younger than 25 weeks. The mean gonadal weight of 10 male foetuses (average age 21.5 weeks) was 41.9 mg and that of 6 female foetuses (average age 22.0 weeks) was 25.3 mg, the difference being significant at the 1% level.

Usually the differentiation of gonads into testes and ovaries

is firmly controlled by the sex chromosome constitution, but this mechanism clearly fails to operate during the development of hermaphrodites. In this situation the differentiation of the gonads will be determined by local conditions, of which body side is one of the determining factors. Gonads situated on the right tend to become testes while those on the left are more likely to develop into ovaries. Our demonstration that the right gonad is normally the larger one seems to offer strong evidence in favour of a causal relationship between increased growth and testicular differentiation in mammals^{9,10}.

It is interesting that in chick embryos of both sexes, the left gonad is larger than the right¹¹. Since in birds the female is heterogametic with XY(ZW) sex chromosomes, in contrast to the situation in mammals, it seems that birds are a mirror image of mammals both as regards gonadal asymmetry and their sex chromosome constitution.

We thank Dr Sylvia Lawler and the staff of the MRC Fetal Tissue Bank for foetal gonads, Mr G. Barrett and Mrs Shantha Kumary Mahadevaiah for technical assistance and Mrs Nona Parry-Jones for the diagram. This work was supported by the Cancer Research Campaign.

Low levels of genetic heterozygosity in Hymenoptera

It has been suggested¹⁻⁴ that organisms with a haplodiploid sex determination system should have reduced genetic variability relative to diploid organisms. In haplodiploid systems such as in bees and wasps (Hymenoptera), unfertilised eggs develop into haploid males and fertilised eggs into diploid females. Thus the frequency with which alleles are exposed to selection in an effectively homozygous state is increased over comparable diploid species. A lower level of genetic variation would be expected for haplodiploid organisms, relative to diploid organisms, for that genetic variation which is not neutral and is expressed in the haploid sex. Thus, measurement of the level of genetic variability in haplodiploid species is of considerable interest in understanding the mechanisms responsible for maintaining the high levels of genetic polymorphism in diploid organisms^{5,6}. For this reason, we have measured the genetic variability in haplodiploid species using the combined techniques of electrophoresis and histochemical staining^{7,8}. As predicted by selection theory, we have shown that the Hymenoptera (haplodiploid organisms) have a lower level of genetic heterozygosity and a lower frequency of enzyme polymorphism than do diploid organisms.

Allelic frequencies for enzyme loci resolved for seven species of solitary Hymenoptera. Although many precedents indicate that specific enzyme phenotypes represent at least one locus, in the absence of genetic crosses or allelic variation, it is difficult to determine whether each isozyme observed is coded in a separate locus. We have therefore been conservative in our estimates. The numerical designation assigned to multiple alleles and multiple loci coding the same enzyme function are based on their relative electrophoretic mobility with '1' being the most anodal. Enzyme (and coenzyme) used: 3 HBDH, 3-hydroxybutyrate dehydrogenase (NAD); HPI, hexosephosphate isomerase; MDH, malate dehydrogenase (NAD); GAPDH, glyceraldehyde-phosphate dehydrogenase (NADP); G3PDH, glycerol-3-phosphate dehydrogenase (NAD); LDH, lactate dehydrogenase (NAD); GDH, glutamate dehydrogenase (NAD); G6PDH, glucose-6-phosphate dehydrogenase (NADP); PGM, phosphoglucomutase; 6 PGDH, 6-phosphogluconate dehydrogenase (NADP); IDH, isocitrate dehydrogenase (NADP); FO, formazan oxidase (tetrazolium oxidase); EST, esterase (nonspecific esterases).

The results of this study for seven species of Hymenoptera are shown in Table 1. Each population represented was collected during a single day at one locality. The mean frequency of polymorphic loci and the mean heterozygosity per locus for the haplodiploid species is significantly lower than those for diploid organisms (Table 2). These results are consistent with substantial portions of observed enzyme variation being selectively not neutral. In addition to detecting selection against specific allelic isozymes, we may also be detecting the results of selection against other genes which are closely linked to those coding the allelic isozymes investigated. Other factors, such as small population size and inbreeding, could depress levels of polymorphism. This explanation is made less likely, however, by the fact that

the Hymenoptera species investigated are solitary and powerful flyers found over wide geographical areas. Partial replicates of the data in Table 1 were done on separate populations of *Sceliphron caementarium*, *Scolia dubia* and *Trypargilum politum*. No significant inbreeding or inter-population differences were found.

It is interesting that the variation in mean heterozygosity for the seven Hymenoptera species representing two superfamilies and seven genera is less than that for seven species within the single genus *Drosophila* and, in addition, is less than that for four species from the rodent genera *Mus* and *Peromyscus* (Table 2). It has been argued that the more homogeneous an environment, the smaller the store of genetic variation maintained⁹⁻¹¹. For our data to be

Table 2 Values for the average frequency of polymorphic loci and average mean heterozygosity for seven Hymenoptera species and thirteen diploid organisms

	Average frequency of polymorphic loci	Average mean heterozygosity
Hymenoptera (from Table 1)	$\bar{X} = 0.266$ s.d. = 0.090 s.e. = 0.034	0.061 0.014 0.005
Diploid organisms*	$\bar{X} = 0.392$ s.d. = 0.185 s.e. = 0.051	0.101 0.039 0.011
<i>Drosophila</i> species*	$\bar{X} = 0.507$ s.d. = 0.184 s.e. = 0.070	0.125 0.035 0.013
<i>Mus</i> and <i>Peromyscus</i> species*	$\bar{X} = 0.255$ s.d. = 0.048 s.e. = 0.024	0.079 0.027 0.013

*Data taken from R. C. Lewontin⁹.

These values were calculated separately for both seven species of *Drosophila* and four species of *Mus* and *Peromyscus*.

consistent with this theory, it would be necessary for the variation in the environmental heterogeneity to be less for the order Hymenoptera than within the genera *Mus* and *Peromyscus* or *Drosophila*.

Inheritance of juvenile shell colour of the oyster drill *Urosalpinx cinerea*

MARINE prosobranchs have been extensively studied to elucidate the origin of their shell colour. Some authors have indicated that shell colour is in the main environmentally determined, that is, by diet^{1–5}, by light⁶, or by salinity⁷. Colour also results from direct genotypic action, for example, the change to adult coloration with maturity in some *Cypraea* species^{8–9}, or the restoration of initial colour patterns after shell repair^{10,11}.

Studies of colour-morph frequencies in natural populations of marine prosobranchs usually make the implicit assumption that colour characteristics are inherited^{12–21}, but it can be argued that the characteristic(s) used are not under close genetic control. Without information from breeding studies, the occurrence of environmental factors, which may affect the results, cannot be assessed. A more appropriate strategy would be to know the

inheritance of a characteristic before attempting large scale field studies.

In the oyster drill *Urosalpinx cinerea* adult shell colour grades from brown to purple-grey, with dark purple and white shells also occurring. Juvenile shells (<15 mm shell length (SL), measured from the siphonal canal tip to the spire apex), however, appear somewhat more discontinuous in colour. Young hatching from capsules deposited in the laboratory are either brown, purple, or albino²² (M. R. Carriker, personal communication). This report describes results of laboratory breeding experiments which indicate that juvenile shell colour is inherited in a manner which can be explained using a triallelic, single-locus genetic model, with a dominance hierarchy among the alleles.

In September, 1972, young *U. cinerea* (<8 mm SL) were isolated from local populations. These animals were raised in individual isolation until the shell length was about 15 mm when they were sexed²³, marked²⁴, and combined in pairs. Pairs were reared in separate cages, and were completely immersed in heated, flowing, seawater (system of Carriker and Van Zandt²⁴) at a temperature of at least 15 °C. *Mytilus edulis*, collected from sites where *Urosalpinx* does not occur, were provided as food; thus no extraneous drills were introduced into the cages.

Egg capsules were allowed to develop in the parents' cage until tinges of pigmentation appeared in the developing shells. The capsules were removed and placed in a hatching cage (screened with stretched nylon hose; average mesh 0.5 mm). Daily sprayings prevented clogging of the screens. As young emerged from their capsules, they were removed and placed in a second, identical cage with mussels (<3 mm valve length). This precluded cannibalism of newly emergent and emerging drills by already emerged siblings.

As the young grew, increasingly larger mussels were required, producing waste-removal problems in the fine-meshed cages due to low water flux. Some of the first groups of young consequently suffered extensive mortality from water fouling. Transferring the young to larger-meshed cages (1.5 mm) as soon as they were large enough to be retained (about 4 weeks after hatching) markedly decreased this mortality. Several groups of young were reared from crosses which suffered extensive mortality; usually only the first group was reared in more successful crosses.

Colour scoring of the external shell colour of newly emerged snails was carried out in seawater under a dissecting microscope, using incandescent lighting. Fourteen pairs produced an F₁ generation. Four crosses (A14, A15, A16 and A18) provided capsules in September, 1973; the remainder began ovipositing in February, 1974.

Three discrete external juvenile shell colours were observed among hatching *U. cinerea*: purple, brown and white. The data obtained were consistent with a triallelic, single-locus genetic model with complete dominance in the order purple > brown > white (Table 1).

With growth, however, subtle shell colour changes occur. For instance, purple bands normally occurring on interior surfaces of *Urosalpinx* shells, sometimes penetrate the shell and appear on the external surface, producing a brown, purple-banded snail, if the bands remain narrow. If the bands diffuse, a brown juvenile becomes a purplish adult. This external expression of normally interior bands is inherited, but more work is needed to establish the exact mode.

Additionally, a purplish hue is generally incorporated with age into the shells, eventually obscuring the juvenile colour. This may result either from genetic modifiers, or from prolonged mussel feeding, as suggested originally by Moore². The contribution of diet to adult shell colour is being investigated.

Prosobranchia in general can be split into two groups by the acid-extractability of their shell pigments. Archaeogastropod pigments which are protein-bound (chromoproteins) resist this procedure²⁶. Pigments elaborated by archaeogastropods are probably either digestive residues or end-products of aborted synthetic pathways^{26,27}. That archaeogastropod shell colour changes with diet^{1,3,5} is thus not surprising.

Table 1 F₁ colour morphs produced by the 14 *Urosalpinx cinerea* pairs

Female genotypes are listed first in the parental/juvenile shell colour column. Only the major juvenile colour allele is given. Because of observed dominance relationships, and without F₂ colour segregation information, recessive alleles could not be definitively established in all crosses. Thus no recessive allelic assignments were made. Expected frequencies (in parentheses) were calculated assuming a single-locus, triallelic segregation model. Two groups of young were reared in cross A14 as the first batch suffered considerable mortality.

Meso- and neogastropod shell colour, however, is not totally independent^{2,4} of diet. *Polinices duplicatus* lightens the colour of its callus with a dietary shift towards increased consumption of *Mya*, but the rest of the shell remains unchanged⁴. Moore concluded that shell-banding in *Thais* results from a mussel diet². Berry and Crothers¹⁷ suggested that the capacity for band expression in *Thais* is genetically controlled, analogous to that of terrestrial pulmonates²⁸⁻³¹. Whether or not a *Thais* becomes banded after feeding on mussels thus depends on its inherited susceptibility. This illustrates the intimate relationship between genotypic and environmental components which influence prosobranch shell colour.

In *Urosalpinx*, the inherited juvenile ground colour can be modified with growth by both genetic (shell-band expression; hue modifiers) and environmental (diet) factors. The degree that each component predominates seemingly depends on the prevalence of certain dietary items. Clearly, care must be exercised in interpreting results of studies of shell colour of marine prosobranchs which assume close genetic control. Controlled breeding experiments are essential as a first step towards unravelling the complex and interrelated mechanisms that produce such morphological characters.

I thank M. Carriker for the loan of his heated seawater system, and R. Hoffmann, F. Grassle, and R. Turner for criticisms of the manuscript. This work was supported by the National Science Foundation.

Acrosomal chromocentre in newt spermiogenesis

STUDY of the distribution of satellite DNA during the later stages of spermiogenesis led to a model in which chromosomes of the mature sperm nucleus are U-shaped with posterior centromeres^{1,2}. We have now studied a closely related chromosome marker—constitutive heterochromatin—and, using C banding techniques³, have found a polarised arrangement of chromocentres in spermatids of several newt species.

Adult *Triturus alpestris*, *T. cristatus* and *T. vulgaris* were captured from their natural habitat near Ulm, south-western Germany; *T. marmoratus* was caught in southern France (Banyuls-sur-Mer) and *Diemyctilus viridescens* was obtained from a dealer. Four hours before they were killed, the animals received an intraperitoneal injection of 0.5 ml of a 3% (w/v) colchicine solution. Testes were cut into small pieces and exposed to hypotonic conditions in distilled water for 30 min. Shortly before centrifugation of the suspension, 0.1 of the volume of 1 mM CaCl₂ solution was added, to prevent clumping. Slides were fixed and prepared according to Evans *et al.*⁴. Only 15 s of denaturation in 0.07 N NaOH was needed to produce C bands by the method of Arrighi and Hsu⁵.

As in many species, including man⁶, chromosomes of *Triturus* have segments of constitutive heterochromatin chiefly in their pericentric regions⁶. Figure 1 shows heterochromatin segments on both sides of the centromeres of chromosomes in spermatogonial metaphase and of bivalents at diakinesis of spermiogenesis in *T. vulgaris*. These segments should also be stainable by C banding at later stages of spermatogenesis.

The typical arrangement of chromocentres in spermatids is shown in Fig. 2. There was conspicuous asymmetry: most of the large, irregularly shaped heterochromatin particles were in the half of the nucleus which later becomes the posterior pole. One large chromocentre,

Fig. 1 Spermatogonial metaphase (a) and diakinesis (b) of *T. alpestris* showing C bands.

however, occupied the anterior pole, which later protrudes, developing a close spatial relationship to the acrosome. Of more than 500 spermatid nuclei at this stage, 67.9% had this clearly recognisable asymmetry. We have designated this isolated particulate of heterochromatin the acrosomal chromocentre. This asymmetrical distribution of the chromocentres in spermatid nuclei at this stage was evaluated quantitatively using 200 well polarised nuclei. For this purpose the nuclear area was divided into two parts, defined by a line drawn at right angles to the diameter which crosses the acrosomal chromocentre (Fig. 2a). There was an average of 11.31 large chromocentres per spermatid nucleus. This corresponds well with the haploid number of chromosomes ($n=12$) and shows that extensive fusion of chromocentres does not occur at that stage of spermiogenesis.

The average number of large chromocentres in the anterior and posterior areas of the spermatid nucleus was 1.94 and 9.37, respectively. The distribution of the dot-like small chromocentres followed a less pronounced but similar pattern.

Shortly before the stage at which the spermatid nucleus becomes asymmetrical by the formation of a protrusion at the anterior pole, the acrosomal chromocentre started to elongate and formed a rod-like structure (Fig. 2b). This extended further, concomitant with the growth of the anterior pole, and became a thread (Fig. 2c) which, because of its typical position at the end of the mature sperm nucleus, can be designated the acrosomal chromonema. Very often, a small knob remained visible in the middle of the thread, and in the best preparations a fine beaded structure could be recognised, especially along the anterior segment (Fig. 2d). A homologous structure was detected in mature sperm nuclei of *T. alpestris*, *T. cristatus*, *T. marmoratus* and *D. viridescens*. Demonstration of the acrosomal chromonema in mature sperm nuclei requires relaxation of their tightly spiralled distal part, which can be achieved by brief treatment with Ca^{2+} and by heating the slides. With the DNA-specific bis-benzimidazol stain (Hoechst 33258), the whole sperm nucleus fluoresced brightly, preventing demonstration of the acrosomal chromonema. After mild treatment with deoxyribonuclease, however, this structure became clearly visible as a brightly fluorescent thread (Fig. 3).

None of the somatic tissues examined showed the peculiar arrangement of chromocentres found in spermatids. Nuclei of cells from liver, kidney, intestine, bone marrow and oviduct have randomly distributed chromocentres after C banding. Thus, the polarised arrangement of chromocentres is specific for the postmeiotic cells during spermiogenesis.

To which chromosomes does the acrosomal chromocentre belong? As well as the segment of pericentric hetero-

chromatin, *T. vulgaris* has a heterochromatic region at the distal segment of the long arm of chromosome 1. This region was discovered by Nardi *et al.*⁶ in premeiotic metaphases and can also be recognised on the largest bivalent in Fig. 1. If the acrosomal chromocentre is formed by this block of distal heterochromatin, Macgregor and Walker's description of U-shaped chromosomes with posterior centromeres would still apply to all centromeres. If the plethodontid salamanders they investigated also have a distal block of heterochromatin forming an acrosomal chromocentre, this would probably not be detectable by their method of *in situ* hybridisation with RNA homologous to the minor component DNA. It is likely that the distal C band is built up by a different kind of satellite DNA, representing a very small part of the total DNA. An alternative model would imply that one of the centromeres migrates to the anterior pole shortly before acrosome formation. New differential staining methods (especially with fluorescent dyes) could help to identify the acrosomal chromocentre with one of the C bands in the chromosome complements of the *Triturus* species we examined. There

Fig. 2 a, Asymmetrical arrangement of chromocentres in spermatids of *T. vulgaris*. b, First stage of elongation of the acrosomal chromocentre (*T. vulgaris*). c, Growth of the anterior pole and further elongation of the acrosomal chromonema (*T. vulgaris*). d, Very late spermatid (left) and mature sperm heads of *T. marmoratus* (centre) relaxed by Ca^{2+} treatment, and of *T. vulgaris* (right) not relaxed.

Fig. 3 Late spermatid of *D. viridescens* stained with Hoechst 33258 after mild treatment with deoxyribonuclease. The acrosomal chromonema is clearly visible as a brightly fluorescent thread in the anterior part of developing sperm head.

could be a functional correlation between the acrosomal chromocentre, its morphological alterations during the final stages of spermiogenesis and the location of the genetic information necessary for the organisation of the acrosome. This correlation is also suggested by the presence of peculiar intranuclear and extranuclear structures in differentiating spermatids of a wide variety of species. These structures are found at the part of the nuclear membrane which is first in close contact with the proacrosome granule and later with the growing acrosome⁷.

Antibody-forming cells in human colostrum after oral immunisation

It has been suggested that feeding infants with human milk reduces the incidence of gastrointestinal infections¹. Although macrophages, lymphocytes and antibodies in the milk are probably important in this protection^{2,3}, the mechanism for the development of specific immunity to enteric pathogens is not known. Human colostrum cells synthesise

IgA (ref. 4), and we have used the haemolysis-in-gel technique to demonstrate that human colostrum contains numerous cells which produce IgA antibodies against the O antigens of commonly encountered *Escherichia coli* bacteria⁵. This suggested that the sensitised lymphocytes had either undergone antigen-induced clonal proliferation within the mammary gland or had homed to that organ from another site after becoming sensitised. Because of reports that gastrointestinal immunisation of germ-free mice led to local⁶ and systemic⁷ production of IgA antibodies, and that cells from Peyer's patches effectively repopulate the ileum of lethally-irradiated rabbits with IgA-producing cells⁸, we have examined the effect of gastrointestinal immunisation on the development of antibody-producing cells in colostrum of humans. We found that oral administration of a non-pathogenic strain of *E. coli* led to the rapid appearance of colostrum cells producing antibodies against the O antigen of the organism.

Three women from our research group consented to ingest 10^8 live *E. coli* 083 bacteria during the last month of their pregnancies. This organism had been used previously to colonise non-pregnant adults (R.M.G. *et al.*, unpublished) and many infants in the first day of life^{9,10} without harmful effects. Therefore, we felt confident that this procedure carried little risk for either the woman or the foetus. The procedure was explained to each subject and verbal consent was obtained. Immediately before ingestion, each subject took 2 g NaHCO₃ to reduce gastric acidity. Before colonisation, samples of serum, parotid fluid and colostrum were collected for the quantitation of antibodies by an enzyme-linked immunosorbent assay^{5,11}, and the *E. coli* in a stool specimen were typed with respect to the O antigen¹². In addition, colostrum was examined for lymphocytes producing antibodies to the lipopolysaccharide (LPS) from the 083 bacteria or a pool of eight more prevalent types of *E. coli* by a modification of the haemolysis-in-gel techniques^{5,13}. Each test was repeated every 3–6 d until the first week *post partum*. In two subjects, a second dose of the bacteria was administered 7 and 10 d after the first.

As previously reported⁵, when a pool of LPS derived from commonly encountered *E. coli* was used as antigen, large quantities of secretory IgA (SIgA) antibodies and numerous IgA-producing cells were found in colostrum (Fig. 1). No consistent change in these values could be related to gastrointestinal immunisation with the *E. coli* of unrelated O type.

Before ingestion of the bacteria, low levels of antibodies to the LPS of *E. coli* 083 were detected in the serum, saliva and colostrum (Fig. 1). Antibodies of the IgA class predominated in the saliva and colostrum and these seemed to be of the SIgA type since the quantitations using an anti- α chain and anti-secretory component (SC) as the enzyme carrier correlated significantly ($r = 0.561$; $P < 0.001$). *E. coli* 083 bacteria, however, were not identified in the stool and cells forming antibodies to the 083 antigen were not detected in the colostrum by the plaque assay before immunisation.

As in infants⁹ and non-pregnant adults (R.M.G. *et al.*, unpublished), ingestion of the *E. coli* 083 did not give rise to symptoms. Furthermore, colonisation with the bacteria was short lived and in none of the individuals did this bacterium dominate the aerobic faecal flora. Most frequently the 083 bacteria could only be identified by serotyping those colonies which were selected by their haemolytic capacity.

Nonetheless, beginning as early as 3 d after the ingestion of the bacteria, cells producing antibodies against the O antigen of the *E. coli* 083 bacteria were detectable in the colostrum from each of the colonised individuals. These cells formed plaques in the presence of developing antisera against α chains or SC, suggesting that the antibodies released were SIgA. The specificity of the plaques produced

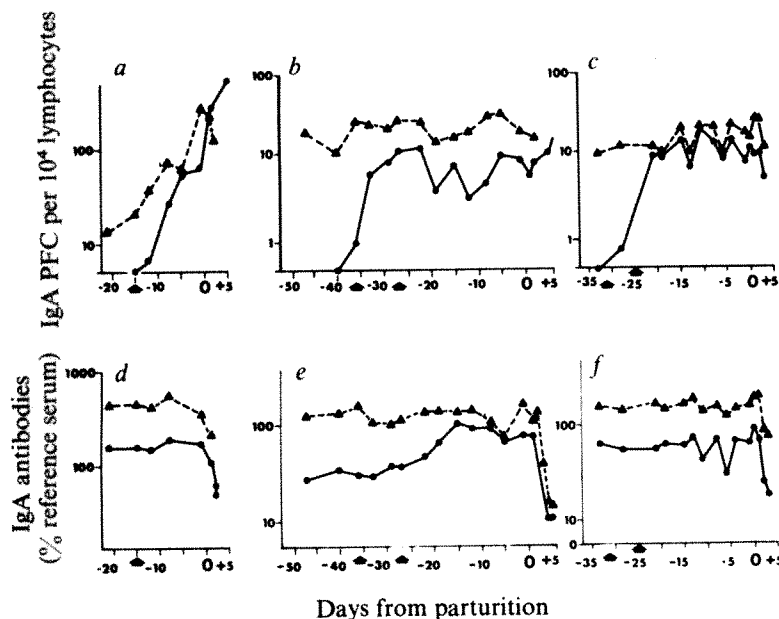

Fig. 1 a-c, Effect of gastrointestinal colonisation with *E. coli* 083 on the number of colostrual cells producing IgA antibodies against O antigen of immunising bacteria (—) or a pool of commonly encountered *E. coli* O antigens (-----). Human red blood cells (RBC) coated with O antigens or uncoated were mixed with colostrual leukocytes in an agar-containing medium. After 1 h incubation (37 °C), anti-immunoglobulin reagents, anti-IgG, anti-IgA or anti-SC (Dakopatts, Copenhagen), were added. Incubation was continued for 1 h, guinea pig complement added for 45 min and plaques counted under oblique light⁸. Significant numbers of plaques were only noted with coated RBC and anti-IgA or SC-developing sera. d-f, Quantity of colostrual IgA antibodies against the same O antigens. Alkaline phosphatase conjugated to the same anti-immunoglobulin reagent was used in the enzyme-linked immunoabsorbent assay⁹. The results are expressed as percentage of the activity of a reference serum. (a,d) (b,e) (c,f) are single individuals; arrows, the time of ingestion of bacteria; each point is the mean of duplicate determinations.

by colostrual cells was verified by inhibition with an excess of purified 083 LPS (250 $\mu\text{g ml}^{-1}$) or by inhibiting protein synthesis with puromycin (10 $\mu\text{g ml}^{-1}$). In one individual, the proportion of lymphoid cells forming IgA plaques against *E. coli* 083 increased logarithmically during the 20 d after a single antigen ingestion. At this point, the number of cells forming plaques against this antigen was greater than that against the pool of eight commonly encountered *E. coli* types (Fig. 1a). In the two individuals who received two doses of the bacteria, the peak number of cells producing antibody against the O antigen of the immunising bacteria was reached after 14 d. The number of anti-083-producing cells in their colostrum approached that of the cells producing antibody against the pooled antigens, and was maintained throughout the remainder of the observation period (Fig. 1b and c).

An increase in the level of IgA antibodies to the 083 bacteria was detected in the colostrum by the enzyme-linked immunosorbent assay after the second dose of bacteria in only one of three immunised individuals (Fig. 1b). In contrast, 083 plaques of the IgM and IgG classes never increased significantly above the background level noted in assays with uncoated erythrocytes and the levels of IgG or IgM colostrual antibodies did not change after immunisation. Further, no increase in salivary or serum antibody of any class was noted.

The disparity between the number of IgA antibody-producing cells and the antibody content of the colostrum, also noted before³, is not explained by the experiments reported here. The finding, however, provides further evidence for *de novo* synthesis of IgA antibodies by colostrual cells.

Two possible mechanisms might be considered to explain the prevalence of colostrual cells producing type-specific IgA antibodies to *E. coli* present in the gastrointestinal tract. (1) The bacteria or their LPS antigens may enter the blood from the gastrointestinal tract and cause a clonal proliferation of the antibody-producing cells or their precursors in the mammary tissue. This seems unlikely because of the mild degree of colonisation and the lack of serum antibody response to the administered organisms. (2) The immunological specificity might be transferred from the gastrointestinal tract to the breast by sensitised cells. Because of the lack of a systemic immune response to the ingested antigens, we favour this possibility. Our experiments do not indicate whether these hypothetical transferred cells are the same as those forming haemolytic plaques or whether they are cells which collaborate in the immune response.

Our observations are supported by the report of SIgA

antibodies in the milk of rabbits fed DNP-bovine γ globulin and DNP-type III pneumococcal vaccine¹⁴, and the occurrence of IgA antibodies against *Salmonella typhimurium* in milk of three women infected with this bacteria during pregnancy¹⁵. Because only free antibodies in the milk were measured in those studies, however, the possibility of transfer of antibody from the serum could not be eliminated.

Our studies indicate a close relationship between antigenic sensitisation by way of the gastrointestinal tract and the development of SIgA antibody-producing cells in the milk. We propose that this phenomenon is due to a selective transfer of sensitised lymphocytes from the gastrointestinal tract to the mammary gland. Since the mother is exposed to the microorganisms which the newborn is likely to encounter, the passive immunity provided by this mechanism could be important in the protection of the infant's gastrointestinal tract.

We thank L. Beijer and H. Lomberg for assistance, Professor A. S. Goldman for discussions and Dr R. Lodinova for *E. coli* 083. Separation of antiviral activity of human interferon from cell growth inhibitory effect

It is well established that potent interferon preparations besides inducing antiviral activity¹, inhibit growth of homologous cells in culture²⁻⁴. In addition, interferon increases the susceptibility of cells to the toxic effects of synthetic double-stranded RNA⁵ and to sensitised lymphocytes⁶, enhances phagocytic activity⁷ and stimulates interferon production by priming⁸. In most studies a close correlation was found between antiviral and non-antiviral activities. The correlation is independent of the degree of purification, and efforts at separation have largely been unsuccessful^{2,5,8,9}, indicating that the effects are attributable to the same substance.

Contradictory findings have also been reported. Some interferon preparations were apparently enriched in one of the effects¹⁰, others contained factors antagonistic to the non-antiviral activities³. A partial separation of effects has also been described¹¹. All these experiments were done with the mouse interferon system. The few data obtained on human interferon^{4,12-14}, although comparable with those found with mouse interferon, are insufficient to characterise the system. Although physicochemical differences have been described, in principle interferons from different species are believed to have an identical mode of action. Recently initiated clinical trials have accentuated the need for a closer examination of the human system. The results reported in this study indicate that it is possible to separate the growth inhibitory effect of human interferon from the antiviral activity by a method based on the selective adsorption of human interferon to albumin. Human interferon was obtained from the supernatant of Sendai virus-induced leukocytes¹⁵. Antiviral activity was assayed by the infectivity inhibition microtest¹⁶. Titres were adjusted to the international standard preparation, 69/19. The preparations were simultaneously assayed for their effect on cell growth. Aliquots of 10⁵ human embryo lung cells (HEL) were seeded into at least five tubes per sample with medium containing interferon, and

Table 1 Growth inhibitory effect promoted by 50 U interferon per ml from different steps during purification of human leukocyte interferon

Purification step	Interferon (U per mg protein)	Reduction in cell count (%)
Crude interferon	0.6 × 10 ³	24
Alcoholic precipitate at pH 4.5	2.0 × 10 ³	22.5
Alcoholic precipitate at pH 5.7	3.0 × 10 ³	23
Alcoholic precipitate at pH 8.1	6.0 × 10 ³	24
Partially purified (Cantell)	7.0 × 10 ³	28

Interferon was induced in human leukocytes by Sendai virus¹⁵. Crude interferon preparations were precipitated with 0.5 M KSCN, the precipitate dissolved in acid alcohol and purified by stepwise elevation of the pH. The partially purified (Cantell) preparation was produced in the same way by Dr K. Cantell, University of Helsinki, Finland. 10⁵ HEL cells per tube were seeded in Eagle's MEM with 2% calf serum. After 3 d of incubation at 37 °C the tubes were treated with trypsin-versene and counted in a haemocytometer. Control tubes without interferon represent 100%.

into control tubes without interferon. Cultures were incubated at 37 °C in a 5% CO₂ atmosphere. On the basis of preliminary studies indicating a straight line dose dependence, 50 U interferon per ml were routinely used. For growth curves at least five tubes were counted every day after trypsin-versene treatment. In a typical experiment 78 × 10³, 130 × 10³, and 244 × 10³ cells per tube were found for the controls at day 1, 2, and 3 respectively against 88 × 10³, 111 × 10³, and 162 × 10³ respectively for the interferon-treated cells. The standard deviation never exceeded 10%. By further incubation the difference between interferon-treated cells and controls levelled off as the control cells entered the stationary phase. On the basis of these results 3 d of incubation were routinely used in tests for cell growth inhibition.

The consecutive steps of purification of the crude interferon preparations, including a highly purified sample from Dr K. Cantell¹⁵ were tested for antiviral and cell growth inhibitory activities (Table 1). The effect on cell growth was strictly correlated to the antiviral effect, regardless of the degree of purification, in accordance with earlier findings^{2,3,5,8}. Interferon preparations were applied to an albumin-Agarose column¹⁷ (Fig. 1). At low ionic strength (phosphate-buffered saline (PBS) (0.15 M NaCl) pH 7.4) the bulk of contaminating proteins could be washed off the column together with unattached interferon. The major part of interferon activity was bound to the column. The eluant was then changed to PBS (1 M NaCl)

Fig. 1 Affinity chromatography of human leukocyte interferon on albumin-coupled Agarose column. CNBr activated Sepharose 4B was swollen in dilute HCl and coupled with bovine albumin by mixing for 2 h. 9 mg of albumin were bound to 1 ml of Agarose beads. Crude interferon, 2 × 10⁴ U in 2 ml, was applied to a PBS equilibrated column. The column was first washed with phosphate-buffered 0.15 M NaCl at pH 7.4. The eluant was changed after the tenth fraction (5 ml each) to PBS (1 M NaCl) at pH 7.4, and after the twentieth fraction to 33% ethylene glycol in PBS (1 M NaCl). All fractions were tested for protein content by the method of Lowry²⁰, antiviral activity, and effect on cell multiplication.

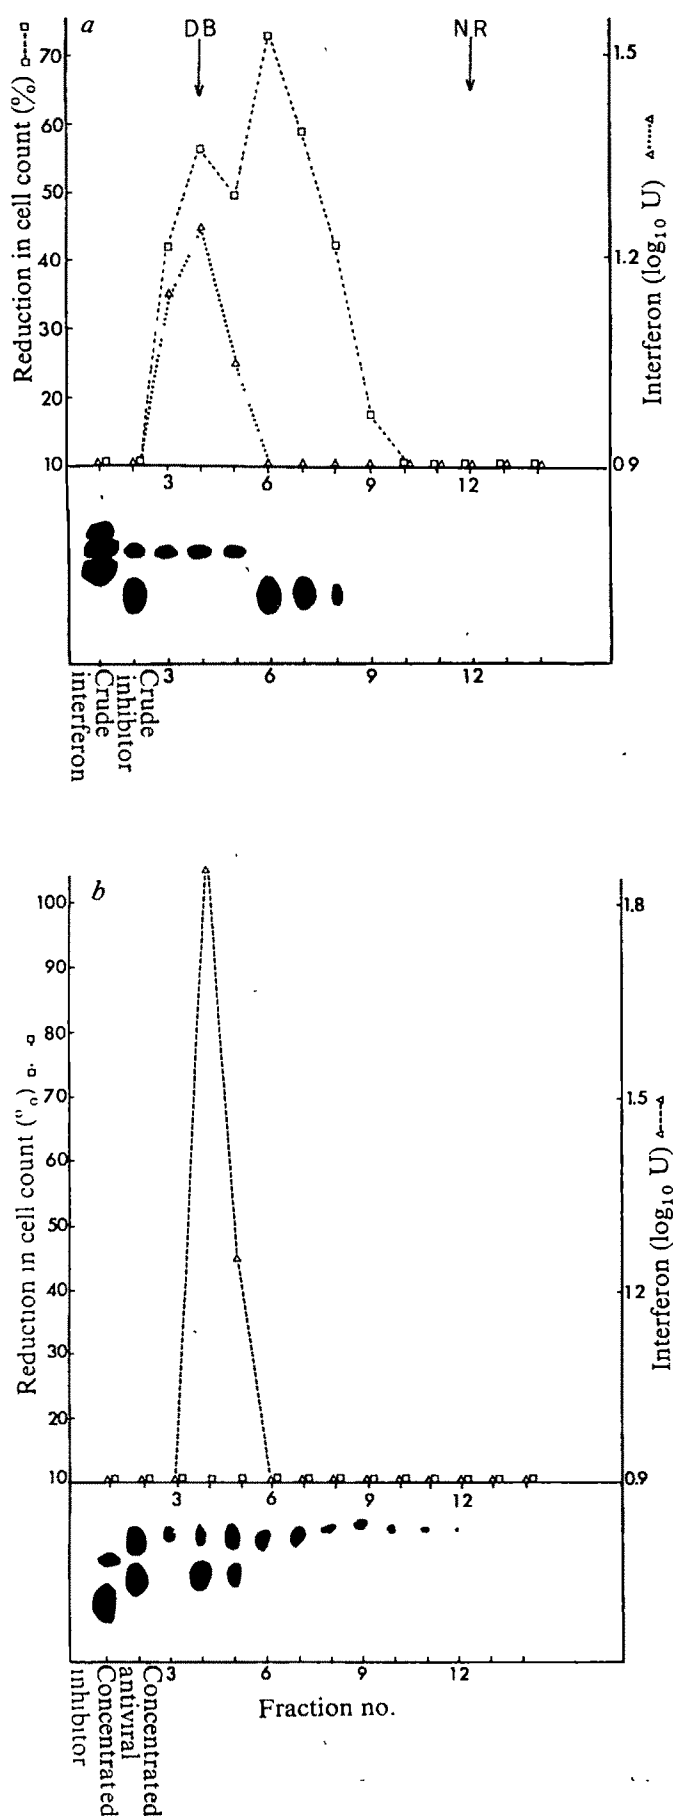

Fig. 2 *a*, Separation of antiviral activity from the effect on cell growth on a Sephadex G-25 column. The fractions from the affinity chromatography, containing cell growth inhibitory effect (Fig. 1, fractions 17-20), were pooled, concentrated by lyophilisation and applied to a Sephadex G-25 column. Each fraction (5 ml) was tested for antiviral activity and for effect on growth of HEL cells in 1:20 dilution. The arrows indicate the appearance of the included markers: DB, Dextran blue, molecular weight 150,000; NR, neutral red, molecular weight 1,000. Thin-layer chromatography of the fractions on Eastman cellulose sheets, developed in alcohol-acetic acid-4% NaOH (50:20:30) and detected in ninhydrin reagents, is shown in the lower part of the figure. Crude interferon and concentrated pool of the fractions containing cell growth inhibitory effect are included as controls. *b*, Analysis of the fractions from the affinity chromatography, containing antiviral activity (Fig. 1, fractions 30-34) on a Sephadex G-25 column. Thin-layer chromatography of the fractions is shown on the lower part of the figure. Preparation and analysis of the fractions as for *a*.

at pH 7.4, which eluted a sharp peak of cell growth inhibitory activity with only a small antiviral effect. The remaining antiviral activity was eluted in a single peak with 33% ethylene glycol in phosphate-buffered 1 M NaCl (v/v) at pH 7.4. These fractions had no effect on cell growth in dilutions containing 100 U interferon, expected to depress the cell growth by 30-40%. Nor was there any detectable effect on the growth of HeLa cells, which were more sensitive than HEL to the effect of unseparated preparations. Control preparations obtained from the supernatant of uninduced leukocytes and chromatographed as the interferon preparations, showed neither antiviral activity against VSV nor effect on the growth of HEL or HeLa cells.

The fractions showing growth inhibitory effect were examined further. Dialysis against PBS eliminated the growth inhibitory effect, suggesting a low molecular substance, distinct from the interferon molecule with reported molecular weight ~ 20,000 (refs 18 and 19). Pooled fractions, concentrated by lyophilisation, were applied to a Sephadex G-25 column (Fig. 2*a*). Antiviral and some growth inhibitory effect were eluted by PBS in the void volume and resulted in a single spot in the thin-layer chromatogram (Fig. 2*a*, lower part). Growth inhibitory effect without detectable antiviral activity was eluted at molecular weight ~ 3,200, and these fractions gave rise to single spots in the chromatogram, but with a different retention factor, indicating the separation of the two effects in distinct molecular components. The antiviral fractions obtained by the affinity chromatography were treated by the same process (Fig. 2*b*). The antiviral activity was eluted in the void volume, and no cell growth inhibition could be detected in any of the fractions. The results were confirmed by thin-layer chromatography: the antiviral fractions resulted in spots with retention factors distinct from those fractions where both activities were detected.

Dialysis of crude human leukocyte interferon against 1 M NaCl resulted in the reduction of the growth inhibition to less than half the normal activity. When the interferon was unfolded by treatment with 5 M urea before dialysis against 1 M NaCl, however, the growth inhibitory activity was completely lost. This result may suggest that the growth inhibitory component is situated inside the interferon molecule and may be released only by forces, which alter the tertiary structure.

The results reported here indicate that the antiviral activity of interferon can be separated from the effect on cell growth by a relatively simple procedure. The separation is probably caused by the high ionic strength indicating that the molecules responsible for the two different effects are bound to each other by electrostatic bonds.

Specific afferent interference by antiserum of *in vivo* immunity

ANTISERUM can potentially interfere with effective immunity at three different parts of the immune response: afferent, central and efferent¹⁻⁶. Coating or masking of antigenic sites on tumour cells with antiserum could render the cells non-immunogenic^{1,2}—called afferent block—or protect them from attack by immune lymphocytes^{3,4}—called efferent block. In central interference, the ability of the lymphocytes to become sensitised against tumour antigens is suppressed, or immune cells are made non-reactive by the humoral factors^{5,6}. Most early studies in this area were performed with tumour allografts or used antisera with antigenic specificities which were not well characterised. Only a few studies have been performed with syngeneic tumours^{7,8}. Because of the complexity of surface antigens expressed on tumour cells, the effects of the antisera on the tumour-associated transplantation antigen (TATA) was therefore difficult to assess.

We have studied the biological effect of well characterised antisera on the induction of *in vivo* immunity to syngeneic tumours. Three such sera were used. (1) Anti-Friend virus-induced leukaemia serum (AFLS), produced by syngeneic immunisation of C57BL/6 mice with FBL-5 cells, a Friend virus-induced leukaemia. This serum recognised three antigenic specificities: Friend type specific, FMR (Friend, Moloney, Rauscher) and cross-reactive foetal antigens⁹. (2) Anti-SV40 tumour serum (ASVS) produced by immunisation of (BALB/c × C57BL/6)F₁ with a syngeneic SV40 tumour. This serum would react chiefly with a SV40 tumour-associated cell surface antigen (TASA)¹⁰. (3) Anti-foetal serum (AFS), produced by immunisation of C57BL/6 mice with syngeneic foetuses. This serum only recognised the foetal antigens expressed on foetal cells or various tumour cells¹¹.

The FBL-3 cells have been shown to be very tumorigenic (intraperitoneal inoculation of 1×10^3 cells would produce progressive tumour growth), and it was also very immunogenic and immunosensitive (immunisation with 1×10^4 X-irradiated cells could produce protection against intraperitoneal inoculation of 1×10^6 FBL-3 cells)¹², and therefore, the FBL-3 cells were very suitable for tests of *in vivo* tumour immunity. In our study, sera of various sources were preincubated with 10,000 r. X-irradiated FBL-3 cells. Serum-treated and untreated cells were then inoculated into B6 mice to determine the effect of serum treatment on the ability of these cells to produce *in vivo* tumour immunity. The results are summarised in Table 1. In experiment 1, 1×10^4 or more untreated irradiated FBL-3 were needed to produce significant protection against challenge with FBL-3 cells. In contrast, 1×10^4 serum-treated cells produced considerably less protection. This blocking of the immuno-

Experiments 1, 2 and 3 were separate, individual experiments. NMS, normal mouse serum. In experiments 2 and 3, 0.4 ml undiluted serum was incubated with 1×10^6 10,000 r. X-irradiated FBL-3 cells at 37 °C for 60 min.

* In experiment 1, 0.2 ml undiluted serum was incubated with 5×10^4 , 5×10^5 or 5×10^6 10,000 r. X-irradiated FBL-3 cells, respectively, at 37 °C for 60 min. After treatment, they were resuspended to 10 ml in Hanks' balanced salt solution, and 0.2 ml of each preparation was inoculated intraperitoneally into each mouse (the mice received 1×10^3 , 1×10^4 and 1×10^5 cells, respectively). Untreated X-irradiated FBL-3 cells were given in the same manner.

† Inoculated intraperitoneally with indicated number of 10,000 r. X-irradiated cells.

‡ Mice were challenged intraperitoneally with viable FBL-3 cells. The challenge doses were 1×10^4 – 1×10^6 in experiment 1, 3×10^5 – 3×10^6 in experiment 2, and 3×10^6 cells in experiment 3. The denominator indicates total number of mice challenged, the numerator indicates the number of mice with tumour growth. The figures in parentheses indicate the percentage of mice with tumours. Mice were observed for tumour incidence for 30–60 d. All control mice died within 14–20 d of challenge.

§ (% Protection obtained with) – (% Protection obtained with) untreated cells treated cells

% Protection obtained with untreated cells

In experiment 1, comparisons were made between groups receiving the same number of cells.

genicity by the antiserum was overcome by immunising with 1×10^5 treated cells. In experiment 2, blocking of immunogenicity was again shown to occur with 5×10^4 cells treated with AFLS, but not with cells treated with normal serum. The specificity of the blocking of anti-tumour protection was further shown in experiment 3. Only AFLS produced a significant interference with the immunisation. Sera produced by immunisation with SV40 (ASVS) or by foetal tissue (AFS) had no significant effect.

To determine whether the blocking effect by AFLS could be explained by toxicity to FBL-3 cells, the following experiments were performed. First, FBL-3 cells treated with AFLS were shown to retain viability *in vitro*, as measured by Trypan blue dye exclusion. Second, normal or immune C57BL/6 mice were challenged intraperitoneally with untreated or serum-treated viable FBL-3. The results are summarised in Table 2. Serum treatment had no effect on unimmunised mice, which indicated that AFLS did not cause significant killing of the FBL-3 cells *in vivo*. Such serum treatment, however, increased the protection in immune mice. The mechanism of this potentiation of established *in vivo* immunity was not clear. It may be due to some augmented effect exerted by antiserum on the effector cells; or the presence of unblocking antibodies in

Table 2 Direct effect of antiserum on growth of FBL-3 cells in normal and immune hosts

this serum to offset the blocking antibody which might be present in these immune hosts^{13,14}. It seemed to be different from the antibody-dependent, cell-mediated cytotoxicity^{15,16}, however, in which specific cytotoxicity could be produced by the interaction of non-sensitised lymphoid cells and specific antiserum.

Our results indicated that specific antiserum could produce afferent interference with *in vivo* tumour immunity by masking the specific antigenic sites and thereby block the immunogenicity of the tumour cells. This effect was not likely to be due to central interference, since inoculation of 1×10^5 serum-treated cells, which involves administration of at least the same amount of antiserum on the coated tumour cells, had no significant blocking effect (Table 1). These results are more consistent with insufficient masking of the larger number of tumour cells by the amount of available antibodies. This finding also indicated that the blocking was not due to an effect on the effector cells; if it was due to elution of antiserum from the coated tumour cells to act on the effector cells, then blocking should be obtained with 1×10^5 treated cells. The mechanism of blocking also did not seem to be related to a direct cytotoxic effect on tumour cells, as shown by lack of protection in normal mice challenged with serum-treated cells (Table 2). Moreover, the interference of *in vivo* tumour immunity was antigenically specific. Only the serum which contained antibodies against the appropriate TASA was effective. This result was similar to those obtained by testing the specificity by immunisation with various tumour cells or foetal cells¹², that is, *in vivo* protection was only obtained by immunisation with leukaemias induced by Friend, Moloney or Rauscher viruses (FRM specific), but not by immunisation with foetal tissue or tumour of other origin. These findings of the inability to interfere with antitumour immunity by anti-foetal serum provide another indication that foetal antigens in this system did not function as transplantation protection antigens. These data also supported the previous reports of the serologically detected TASA being a transplantation antigen^{9,12}.

This study has shown that only the specific antitumour antiserum can produce afferent interference of the *in vivo* tumour immunity. Thus, when well characterised, specific antisera are used, it can also help to test the specificity of TASA.

Interaction between lectin from *Ricinus communis* and liposomes containing gangliosides

A MODEL has been presented showing the contribution of the protein-glycoprotein complex^{1–3} when transformed cells are agglutinated by lectins^{4–6}. But this has not been possible for the lectin-glycolipid complex because glycolipids form micelles, even at very low concentrations. This difficulty could be overcome by incorporating these glycolipids into lipid vesicles. (Haywood demonstrated that ganglioside incorporated in liposome can provide receptors for sendai virus⁷.) We have now studied the interaction between a galactose-specific lectin from *Ricinus communis* beans^{1,8,9} and liposomes containing different amounts of monosialoganglioside (GM₁), and found that the latter can be used as a model system for the investigation of agglutination of cells by lectins.

Gangliosides GM₁, GM₂, GD_{1a} and GT₁ (according to Svennerholm's nomenclature¹⁰) were isolated by thin-layer chromatography (TLC) from beef brain ganglioside prepared by the method of Folch *et al.*¹¹ Individual gangliosides were more than 90% pure as judged by TLC. *R. communis* lectin was purified as before¹ and lipid vesicles¹² were prepared by Huang's

Fig. 1 Binding of RCA₁ to liposomes of different ratios (*R*) of phospholipid to GM₁ at 4 °C. Various amounts of RCA₁ were added to a liposome suspension containing 6.4 nmol of GM₁ in 0.05 M phosphate buffer, pH 7.0, containing 0.15 M NaCl. The total volume of incubation medium was kept to 2 ml. Top, SC liposome: ○, *R* = 123; □, *R* = 55; ●, *R* = 22.8; ■, *R* = 12. Bottom, MC liposome: ▲, *R* = 147; △, *R* = 43.5. Inset, amount of RCA₁ bound as a function of ratio of GM₁ to phospholipid (1/*R*).

method¹³. Phospholipid (synthetic β - γ -dipalmitoyl-DL- α -lecithin, Sigma) and cholesterol (three times crystallised) in the molar ratio 2:1, with various concentrations of the different gangliosides (0.02–0.1 mol per mol of phospholipid) were dissolved in 2:1 chloroform-methanol. The solvent was subsequently removed under reduced pressure at 25 °C, and the flasks were placed in a vacuum desiccator for 4 h. The lipids were then suspended in 0.02 M Tris-HCl buffer, pH 7.4, containing 0.15 M NaCl and sonicated for 2 h under nitrogen at 4 °C. The liposomes thus obtained were centrifuged at 5,000g for 30 min to remove titanium particles and then subjected to gel filtration on Sepharose 4B to separate single compartment (SC) from multi-compartment (MC) liposomes described by Huang¹³. The fractions of SC and MC liposomes were pooled separately and concentrated to 1 ml. The amount of dipalmitoyl lecithin and ganglioside in the liposome was calculated by estimating lipid phosphorous¹⁴ and *n*-acetylneuraminic acid¹⁵, respectively. About 93% of phospholipid and 90–95% of gangliosides were incorporated in these liposomes. Thus liposomes containing GM₁, GM₂, GT₁ and GD_{1a} had been prepared.

Binding studies were done at 4 °C by adding various concentrations of lectin to the different batches of liposomes containing a constant amount of various glycolipids in 0.05 M sodium phosphate buffer, pH 7.0, containing 0.15 M NaCl. The tubes were constantly shaken and after 3 h they were centrifuged at 105,000g for 2 h. The lectin remaining in the supernatant was estimated for protein by Lowry's method¹⁶ and subtracted from the amount added to give the amount bound to liposomes.

Liposomes without GM₁ and GM₂, GT₁ and GD_{1a} did not bind lectin whereas those containing GM₁ showed considerable binding (Fig. 1). Since all the lectin was recovered in the supernatant in the case of liposomes without GM₁, in the conditions of the binding experiment these way no significant entrainment of lectin. The association constant K_a (mol⁻¹) for the binding of incorporated GM₁ to lectin was calculated according to equation (1) from the value of m at $\theta = 0.5$.

$$K_a = \frac{\theta}{(1-\theta)m} \quad (1)$$

(where m = concentration of RCA₁ free in solution and θ = fraction of GM₁ at the outer surface in liposome, bound to RCA₁).

K_a thus calculated has a value of 2.2×10^6 mol⁻¹. Table 1 shows that about 27% and 60% of total GM₁ in liposome is available to bind to lectin at the outer surface of MC and SC liposomes, respectively. This agrees well with the amount of

Fig. 2 Typical run for the kinetics of SC liposome aggregation on mixing with RCA₁ at 28 °C. MC	12.0	0.275 (43.5)	403.0	27 (30 ± 3%)	—	2.20

The results presented in columns 5, 6, 7 and 8 are the average of three independent experiments.

*Dipalmitoyl lecithin and ganglioside (GM₁) in liposome was calculated by estimating lipid phosphorous¹⁴ and *n*-acetylneuraminic acid¹⁵, respectively.

†Numbers in parentheses indicate values of R (phospholipid per GM₁).

‡GM₁ available at the surface was calculated using a saturation value for RCA₁ considering RCA₁ bivalent

This was confirmed by preparing GD_{1a} liposome and subjecting it to *Vibrio cholerae* neuraminidase.

§The number of molecules of *n*-acetylneuraminic acid liberated from these liposomes corresponds to the amounts of GD_{1a} molecules accessible to hydrolysis by neuraminidase (that is exposed on the outer surface of liposome). This number is indicated in parentheses under ‡.

§Based on the molecular weight of SC liposome as 2×10^6 daltons and its diameter as 300 Å (ref. 13).

¶For a 1-ml reaction mixture containing 1.73×10^{-7} mol of GM₁ and 3×10^{-6} mol of RCA₁.

suggesting that there was no binding of free GM₁ with lectin.

When lectin was added to liposome containing GM₁, the absorbance (that is turbidity) at 320 nm increased with time presumably due to the formation of liposome clusters which resemble cell agglutination. The rate at which turbidity increased at 320 nm was dependent on the composition of the liposome, that is on the number of lectin binding sites per μm^2 , although K_a remained constant. Figure 2 shows the typical kinetic run for SC liposomes with different ratios of phospholipid to GM₁ (R values), carried out with lectin in excess GM₁ available at the outer surface (pseudo-first order conditions). From the slope of plot of $\log(A_\infty - A_t)$ against t (where A_t and A_∞ are the absorbance at time t and infinity) the pseudo-first order rate constant k_{obs} is calculated. There from the second-order rate constant of cluster formation, $k_f = (k_{obs}/C)$, where C is the concentration of lectin in mol^{-1} based on a molecular weight of lectin of 120,000) are summarised in Table 1. It is interesting that a factor of two increase in available binding sites for lectin leads to an increase in the rate constant of formation by a factor of 20. The k_f value for GM₁ liposome ($R = 55$) is comparable with that for the glycoprotein-concanavalin A (Con A) system¹, whereas k_f for the liposome ($R = 22.8$) is comparable with that for the 'precipitin' reactions between glycogen and con A¹ and between guar gum and *R. communis* lectin. The latter values compare well with the rate constant of $8 \times 10^4 \text{ mol}^{-1} \text{ s}^{-1}$ for the formation of the soluble con A-carbohydrate complex, reported by Gray and Glew¹⁸.

From our measurements we draw the following conclusions. (1) The incorporated gangliosides are recognised through the non-reducing terminal galactose moiety; this is consistent with our studies with galactose-containing glycoproteins¹⁹. (2) The K_a of this interaction is 100–1,000 times greater than those of galactose and *p*-nitrophenyl- β -D-galactopyranoside, respectively^{1,9}. This value may arise from any of the following and/or any combination of (i) interaction of protein component with the lipid matrix, (ii) different conformations of carbohydrates of the glycolipid when embedded in lipid phase and when free in solution, (iii) alteration of the polarity of the intervening medium due to the presence of the glycolipid cluster. Any differences in these factors may lead to slight differences in K_a values calculated from the 50% saturation values. (3) The rate constant of cluster formation is significantly altered depending on the number of sites per μm^2 of liposome surface which are likely to be uniformly distributed, whether they are MC or SC. This suggests that GM₁ in liposome which are available to bind with lectin with more or less the same affinity are kinetically distinguishable when the ratios of GM₁ and phospholipid in the liposome are varied. The reason for this is not clear. It may be because GM₁ is differently located in the lipid matrix or because surface diffusion controls the rate of formation of clusters, as measured by increased turbidity. Nevertheless our findings are consistent with the idea that the observed increased agglutinability of transformed cells is mediated through (1) change in the topological distribution of receptor site and (2) membrane fluidity. Further studies are required to assess quantitatively how the membrane fluidity (determined by the nature and composition of lipid matrices) influences the kinetic behaviour of cluster formation representing cell agglutination.

Differential effects of glucocorticoids on DNA synthesis in normal and virus-transformed chick embryo cells

Loose connective tissue fibroblasts in the mouse become markedly non-motile and refractile and lose pinocytotic activity within about an hour of hydrocortisone infusion. Only minutes are required to mimic this response in culture¹. These responses of fibroblasts are well correlated with the topical anti-inflammatory potency of the glucocorticoids². Glucocorticoids inhibit the multiplication in primary cultures of rat and mouse fibroblasts and of human epithelial cells^{3–6}. In marked contrast, they stimulate multiplication of 3T3 cells⁷. Some investigators regard the 3T3 cell as a prototype for the study of growth regulation in

Fig. 1 Inhibition by glucocorticoids of DNA synthesis in cultures of chick embryo cells. 10^6 chick embryo cells were seeded in 60-mm Petri dishes. After 3 d growth, the medium was changed to one without serum, and one of three glucocorticoids was added at the indicated concentrations for 16 h. The rate of ^3H -TdR incorporation into DNA for 1 h was measured by extraction and scintillation counting, and the total protein content was measured¹². \circ , Dexamethasone; Δ , hydrocortisone; \square , cortisone. We used published cell and virus culturing techniques^{9–11}. DNA synthesis was measured by the incorporation of ^3H -thymidine (^3H -TdR) into extractable DNA, or by autoradiography¹². Protein was determined by the Lowry method for cells in culture¹². Glucose transport was measured by the uptake of ^3H -2-deoxy-D-glucose (^3H -2dGlc)¹². In several preliminary experiments, we observed that glucocorticoids did not affect DNA synthesis in chick embryo cultures if the hormones were added to medium conditioned by one or more days of exposure to growing cells. We therefore carried out all experiments with cultures that received fresh changes of medium.

Fig. 2 Kinetics of inhibition and restoration of DNA synthesis in chick embryo cultures after hydrocortisone treatment and removal. Cultures of chick embryo cells were treated for 16 h with serum-free medium (a) or with serum-free medium containing 10^{-7} M hydrocortisone (b). The following media then were substituted in both groups: Δ , 1% serum, no hydrocortisone; \square , 1% serum, with hydrocortisone; ∇ , no serum, no hydrocortisone; \circ , no serum, with hydrocortisone. At the indicated times, the incorporation for 1 h of ^3H -TdR into DNA was determined.

cultured fibroblasts, although this line has been identified as tumorigenic in some conditions⁸.

We have determined the effects of glucocorticoids on primary chick embryo fibroblast cultures in which a variety of growth-regulatory parameters were measured, and on the same cells after they had undergone virus-induced malignant transformation. We found that the glucocorticoids in very low concentrations retarded the progress of normal chick embryo fibroblasts through the G_1 period of the cell cycle, thereby reducing the fraction of cells synthesising DNA at any given time. The same concentrations of glucocorticoids had no effect on the initiation of DNA synthesis in virus-transformed cultures.

Figure 1 shows the effects of treatment for 16 h with each of three glucocorticoids on DNA synthesis in normal chick embryo cells. (We chose 16 h after hormone treatment as the time for measuring maximum inhibition of DNA synthesis, as shown in Fig. 3.) All three glucocorticoids reduced ^3H -TdR incorporation into DNA about four- to sixfold. Levels of 1.5×10^{-10} M dexamethasone, 4.5×10^{-10} M hydrocortisone and 1.5×10^{-9} M corticosterone caused 50% inhibition of DNA synthesis. These levels are all within the physiological concentration range of glucocorticoids¹³.

We measured the kinetics of inhibition and restoration of DNA synthesis by hydrocortisone in the presence or absence of serum. Inhibition of DNA synthesis definitely was evident both in the presence and absence of serum within 4 h of administration of the hormone, and inhibition became more pronounced with time up to 10 h (Fig. 2a). Similarly, increased DNA synthesis was apparent within 4 h of removal of hydrocortisone and became more pronounced with time up to 10 h (Fig. 2b). Inhibition by the hormone of the rate of incorporation of ^3H -TdR into extractable DNA was proportional to reduction in the fraction of nuclei labelled with ^3H -TdR, as detected by autoradiography (Fig. 3).

The uptake of ^3H -2-dGlc into uninfected cells was inhibited more rapidly than was the incorporation of ^3H -TdR

into DNA, but the extent of inhibition at 16 and 24 h was about the same for both substances (Fig. 4). Hydrocortisone in concentrations as high as 1.0×10^{-5} M had no effect on DNA synthesis in cultures of chick embryo fibroblasts transformed by infection with Rous sarcoma virus (Table 1).

These data indicate that the growth of normal fibroblasts in primary culture is inhibited by glucocorticoids, just as it is in the animal. This result contrasts markedly with the stimulatory effect of glucocorticoids on the growth of the 3T3 cell line⁷, which has been widely accepted as the prototype of normalcy for fibroblasts in culture. The demonstration that 3T3 cells produced haemangioendotheliomas in mice in certain conditions⁸ raises serious questions about the use of 3T3 cells for studying growth-regulatory processes. These doubts are accentuated by the paradoxical response of the cells to glucocorticoids.

Fig. 3 Comparison of scintillation counting and autoradiography in measuring effects on DNA synthesis with time after hydrocortisone treatment. Cultures of chick embryo cells were treated for various times with 10^{-7} M hydrocortisone in the presence or absence of 1% serum. ^3H -TdR incorporation into DNA was measured by extraction and scintillation counting (a), and by autoradiography (b). ∇ , 1% serum, no hydrocortisone; Δ , 1% serum, with hydrocortisone; \circ , no serum, no hydrocortisone; \square , no serum, with hydrocortisone.

We have shown that the inhibition of growth by glucocorticoids is associated with a reduction in the number of cells synthesising DNA that is proportional to the reduction in ^3H -TdR incorporation into extractable DNA. This indicates that glucocorticoids have no effect on DNA chain elongation and act by slowing the progress of cells through the G_1 period of the cell cycle. Thus, the effect is similar to that produced by increasing population density or by

Table 1 Comparative effect of hydrocortisone on normal and virus-transformed chick embryo cells

Hydrocortisone (M)	^3H -thymidine (c.p.m. per μg protein)* Uninfected	^3H -thymidine (c.p.m. per μg protein)* Transformed
Control	13.54	101.70
10^{-7}	2.95	117.20
10^{-6}	3.01	112.46
10^{-5}	3.05	103.44
10^{-4}	2.75	30.46

*Average of duplicates 16 h after initiation of treatment. Cultures were prepared as described in Fig. 1, and half were infected with the Schmidt-Ruppin strain of Rous sarcoma virus (1×10^6 focus-forming units). The medium was changed on both sets of cultures after 36 h and again on day 3. The latter change of medium contained the indicated hydrocortisone concentrations. ^3H -TdR incorporation into DNA was measured 16 h after hormone treatment.

Fig. 4 Kinetics of inhibition by hydrocortisone of $^3\text{H-2-dGlc}$ uptake and $^3\text{H-TdR}$ incorporation. The medium of 3-d-old chick embryo cultures was changed to one without serum, and 10^{-7} M hydrocortisone was added to half the cultures. At the indicated times, measurements were made of $^3\text{H-2-dGlc}$ uptake into acid-soluble material and of the incorporation of $^3\text{H-TdR}$ into acid-insoluble material. Protein content was determined by the Lowry method. ○, $^3\text{H-2-dGlc}$; △, $^3\text{H-TdR}$.

lowering either serum concentration or pH (ref. 11). Glucocorticoids produce the same inhibitory effect as these treatments on the uptake of $^3\text{H-2-dGlc}$ and have similar rapid kinetics.

Overall, these results suggest that inhibitory treatments act through a common mechanism related to the hypothetical mechanism by which diverse growth-stimulatory agents act^{14,15}. In the latter hypothesis, the coordinated control of many processes in chick embryo cells is effected through regulation of the availability of divalent cations for enzymatic reactions and other cellular functions¹⁵. The most important of the cations for metabolic control is Mg^{2+} , because of its essential role in transphosphorylation reactions which are the regulatory steps in many biochemical pathways. A mechanism for control of divalent cation activity is suggested by the observation that the stimulatory hormone insulin, decreases the binding of Ca^{2+} to plasma membranes, whereas hydrocortisone increases that binding¹⁶. Substances that modulate Ca^{2+} binding to membranes are also likely to affect Mg^{2+} binding as well, as both cations have similar binding properties for membranes¹⁷. The availability of Mg^{2+} for metabolic processes depends on its partitioning between free and membrane bound forms¹⁷.

Hydrocortisone failed to inhibit DNA synthesis in virus-transformed cultures at a concentration almost 10^5 times higher than that which produces 50% inhibition in normal cells. This observation supports the claim that tumour cells lose their sensitivity to the insulin-anti-insulin set of controls found in normal cells¹⁸. The regulatory mechanism proposed above suggests that membranes of tumour cells have diminished capacity for binding divalent cations and that this characteristic cannot be modified by glucocorticoids. Information on whether this is an intrinsic defect of the membrane or a response conditioned by the internal cell milieu should shed some light on the mechanism of carcinogenesis.

Differentiation of wound vessel members without DNA synthesis, mitosis or cell division

THE formulation of a general model of gene regulation in eukaryotic organisms would be facilitated were it known when the molecular events responsible for reprogramming of genetic information occur during the cell cycle. Evidence from various systems in which animal cells differentiate *in vivo* and *in vitro* suggests that certain characteristics of the fully differentiated state are not manifest until the cells undergo DNA synthesis and nuclear division¹. Similarly the differentiation of wound vessel members (WVM) in plant parenchyma tissue is thought to occur only after cells have replicated at least once in inductive conditions².

WVM are highly specialised elements of the xylem which differentiate in parenchyma tissue as a response to wounding. They are characterised by the deposition of a patterned cellulose secondary wall which becomes lignified and remains as a resistant structure when the cell contents undergo autolysis at maturity (Fig. 1). Dalessandro and Roberts³ observed WVM formation when caffeine was used to inhibit cytokinesis. They considered their results to be inconclusive, however. Other references^{4,5} have been made to WVM formation without cell division but these reports have been based only on the relative sizes of WVM and surrounding undivided parenchyma cells.

I report here the differentiation of WVM without DNA synthesis, mitosis or cell division in cultured explants of Romaine lettuce (*Lactuca sativa* L. cv Romana). Cylindrical disks of parenchyma tissue, 5 mm in diameter and 1.5 mm thick, were isolated aseptically from the pith of Romaine lettuce heads and placed basal end down on a chemically defined medium⁶ containing the DNA synthesis inhibitor fluorodeoxyuridine (FUDR) (10^{-6}M). The numbers of WVM and parenchyma cells were assayed after 14 d of incubation.

Fig. 1 Immature WVM and parenchyma cell in Feulgen-stained squash preparation. Photographed with partially polarised illumination to highlight the birefringent secondary wall of the WVM. Both cells are nucleate (arrows). Bar represents 50 μm .

The results of a representative experiment are presented in Table 1. Disks placed on a medium without FUDR underwent extensive proliferation, as expected, producing approximately 25 times the original number of cells, 7% of the final cell number being WVM. In disks grown on medium with FUDR 6% of the cells differentiated into WVM without any apparent increase in cell number.

There was considerable variation in the number of WVM produced in the presence of FUDR; the average number per disk ranging between 0 and 9×10^3 . This variation was probably due to seasonal effects and to the commercial origin of the plant material. Results were, however, consistent within single experiments.

Table 1 Parenchyma cells and wound vessel members in tissue disks incubated with or without FUDR

	Parenchyma cells ($\times 10^3$)	Wound vessel members ($\times 10^3$)
0 d	87.9 ± 5.6	0
14 d (no FUDR)	$2,240 \pm 220$	180 ± 13
14 d (10^{-5} M FUDR)	79.0 ± 3.8	4.7 ± 1.2

Parenchyma cells and WVM in tissue disks incubated with or without FUDR. Heads of Romaine lettuce were purchased at a local retail outlet, defoliated and surface-sterilised with 0.5% sodium hypochlorite. Cylinders of tissue 5.0 mm in diameter were removed from the centre of the core with a sterile cork borer and sliced into disks 1.5 mm thick. Disks were placed with their morphological basal end down on sterile medium⁶ containing indole-3-acetic acid (10 mg l^{-1}), kinetin (6-furfurylaminopurine, 0.1 mg l^{-1}) and 0.9% rehydrated Difco agar in 6-cm diameter Petri plates. FUDR was filter-sterilised and added to the medium when it had partially cooled. The tissue disks were cultured in the dark at $25 \pm 1^\circ \text{C}$ and at the end of the incubation period dispersed in chromic acid-HCl solution by drawing through a 22-gauge needle⁶. Cell counts were made in six 5- μl samples of an appropriate dilution of the macerate placed on a microscope slide.

Parenchyma cells of the pith are, *in situ*, quiescent and DNA synthesis does not begin for at least 20 h after isolation of the explants (unpublished). Although this seemed more than enough time for the uptake of FUDR in quantities sufficient to inhibit DNA synthesis, the effectiveness of the inhibitor was tested directly by microspectrophotometric measurement of the DNA content of Feulgen-stained nuclei (Fig. 2).

All nuclei of freshly isolated pith contained the 2C level of DNA, confirming earlier reports^{7,8} that cells of this species arrest exclusively in the G_1 phase of the nuclear cycle. In the nuclei of cells grown for 14 d on medium without FUDR the DNA content ranged between 2C and 4C. In FUDR-treated disks, however, there was no measurable DNA synthesis in the nuclei of parenchyma cells. The DNA content of nuclei in 50 immature WVM which had not yet undergone autolysis was also measured. These cells were unambiguously identified as WVM by the presence of secondary walls in the characteristic reticulate pattern (Fig. 1). The amount of nuclear DNA in WVM which had just begun to differentiate corresponded to the 2C level. As these cells continued to differentiate chromatin condensed, leading to an increase in self-absorption and slightly lower values of relative DNA content.

Mitosis and cell division could not have occurred in FUDR-treated disks since all cells were originally in G_1 and did not synthesise measurable amounts of DNA. To verify this conclusion, freshly isolated disks were placed on medium containing FUDR (10^{-5} M) and removed at 12 h intervals for the next 14 d. The disks were stained with Feulgen and squash preparations were systematically and thoroughly examined. WVM were first detected after 5 d of incubation and reached a maximum of approximately 2×10^3 per disk by day 12. No mitotic figures were found in any of the preparations.

The Romaine lettuce-xylogensis system is particularly significant in that the cells which differentiate are apparently uncommitted to the formation of vessel members before isolation. The pith tissue of this species is composed of a

homogeneous population of parenchyma cells devoid of vascular tissue. Xylem elements form only as a response to injury and do not normally differentiate in the pith during the life cycle of an undisturbed plant. In seedlings of wheat germinated from gamma-irradiated grain, differentiation of complex tissues, including xylem, takes place without DNA synthesis⁹. But vessels arise only in procambial tissue already formed in the embryo and presumably committed to differentiation¹⁰. Similarly, there have been reports that, in appropriate conditions, determined mammalian¹¹ and insect^{12,13} cells may differentiate without DNA replication.

Evidence linking differentiation to a previous round of cell division has often led to the suggestion that events during the cell cycle, especially in the DNA replication phase, are themselves integral components of a genetic reprogramming mechanism (reviewed in ref. 14). While most plant and animal cell differentiation undoubtedly occurs after cell division, the experimental uncoupling of these processes suggests that this is not a causal association. In the meristem, cell doubling may be an added constraint on differentiation to ensure that progenitor cells are reproduced before differentiation occurs. A homeostatic mechanism of this nature would protect the integrity of the progenitor cell line *in vivo* and may be responsible for the frequently observed coincidence of cell division and

Fig. 2 Relative amounts of DNA per nucleus before and after 14 d of incubation (Table 1). *a*, Freshly isolated parenchyma cells, sample size (N) = 400. *b*, Parenchyma cells after 14 d incubation no FUDR in medium, N = 165. *c*, Parenchyma cells after 14 d incubation, 10^{-5} M FUDR, N = 400. *d*, Immature WVM after 14 d incubation, 10^{-5} M FUDR, N = 50. Disks of tissue were fixed in ethanol-acetic acid (3:1 v/v), hydrolysed in 5N HCl for 60 min at room temperature and stained by the Feulgen method. The stained preparations were placed in a 5% pectinase solution for 2 h and drawn through a 22-gauge needle to separate cells before mounting in Canada balsam. Measurements of relative DNA per nucleus were made with a Zeiss scanning microspectrophotometer at 560 nm and normalised with readings of half telophase and prophase mitotic figures taken to be 2C and 4C values, respectively.

differentiation *in vitro*. Such a mechanism might also operate where animal cells differentiate in proliferating tissue.

I thank Professor A. C. Braun for encouragement and advice and Dr J. Van't Hof, Brookhaven National Laboratory, for discussions and the use of the scanning microspectrophotometer. This research was supported in part by a research grant from the National Cancer Institute, to Professor Braun.

Stimulation of phosphorylation and inactivation of pyruvate dehydrogenase by physiological inhibitors of the pyruvate dehydrogenase reaction

OXIDATION of pyruvate in perfused rat heart is inhibited by diabetes and by oxidation of fatty acids and ketone bodies¹. Enhanced release and oxidation of fatty acids from muscle glycerides may be an important factor in the effects of diabetes²⁻⁴. These effects on pyruvate oxidation have generally been attributed to inhibition of pyruvate dehydrogenase, and regulation of this enzyme is considered to be of crucial importance in the selection of fuels for respiration and in the metabolic changes in heart and other tissues in diabetes and starvation.

Mammalian pyruvate dehydrogenases contain three enzymes, pyruvate decarboxylase (E_1), dihydrolipoate acetyl

transferase (E_2) and dihydrolipoate dehydrogenase (E_3) bound together in a single complex. They catalyse the conversion of pyruvate, CoA and NAD into acetyl CoA, NADH₂ and CO₂ in the presence of Mg²⁺ and thiamine pyrophosphate (TPP) by a coordinated series of reactions in which lipoate bound covalently to the acetyl transferase visits active sites on the three enzymes sequentially. Lipoate reacts with hydroxyethyl TPP formed on E_1 to give acetyl hydrodipoate which reacts with CoA on E_2 to form acetyl CoA and dihydrolipoate, the latter then reacts with NAD on E_3 to form NADH₂ and regenerate lipoate⁵. Reversible reactions are catalysed by E_2 and E_3 , whereas the reaction catalysed by E_1 is essentially irreversible. NADH₂ can thus form dihydrolipoate, and acetyl CoA plus NADH₂ can form acetyl hydrodipoate and hydroxyethyl TPP within the complex by reversal of reactions catalysed by E_2 and E_3 .

Pyruvate dehydrogenase in heart muscle or liver is subject to end product inhibition by acetyl CoA (competitive with CoA) and NADH₂ (competitive with NAD) and this inhibition is presumed to be due to accumulation of acetyl hydrodipoate and dihydrolipoate within the complex^{6,7}. Mammalian pyruvate dehydrogenases are also regulated by pyruvate dehydrogenase kinase within the complex, which catalyses phosphorylation and inactivation of pyruvate decarboxylase with ATP-Mg²⁺; a phosphatase catalyses dephosphorylation and reactivation^{8,9}. In perfused heart oxidation of fatty acids or ketone bodies leads to a substantial increase in the concentration ratio of acetyl CoA-CoA. With acetate, for example, this ratio increases sixtyfold and oxidation of pyruvate is almost totally suppressed within 1 min of entry of acetate into the coronary circulation^{10,11}. It has been suggested that this change in concentration ratio may lead to end product inhibition of pyruvate dehydrogenase and thus contribute to inhibition of pyruvate oxidation. In perfused heart oxidation of fatty acids and ketone bodies also stimulates phosphorylation and inactivation of pyruvate dehydrogenase^{12,13}. The mechanism of this effect is not known but it presumably involves activation of the kinase reaction or inhibition of the phosphatase reaction or both.

The known effectors of the kinase reaction (ADP, pyruvate, pyrophosphate compounds, Ca²⁺ and Mg²⁺ as inhibitors) and of the phosphatase reaction (Mg²⁺ and Ca²⁺ as activators^{8,9,14,15}) did not provide an obvious explanation of effects of fatty acids and ketone bodies in the perfused

Table 1 Effects of NAD, NADH₂, CoA and acetyl CoA on activity of pig heart pyruvate dehydrogenase kinase

Pig heart pyruvate dehydrogenase (2 U ml⁻¹) was incubated at 30 °C for 1.5 min in 20 mM potassium phosphate, 5 mM 2-mercaptoethanol, pH 7.0 (volume 50 μ l) with γ -³²P-ATP (100 μ M, 8 μ Ci μ mol⁻¹) and 2 mM MgCl₂ with other additions as shown. The reaction was terminated and protein-bound phosphate assayed in 30 μ l samples as in ref. 15. The number of assays is shown in parentheses.

heart. It seemed likely that the concentration ratios of acetyl CoA-CoA and of NADH₂-NAD might modulate kinase or phosphatase reactions in addition to their effects on the dehydrogenase reaction. No consistent and significant effects of NAD, NADH₂, acetyl CoA or of CoA on the phosphatase reaction¹⁶ have been detected. Attempts to demonstrate effects of the concentration ratio of acetyl CoA-CoA on the kinase reaction yielded very variable results¹⁵. Recent studies of elementary reactions in the pyruvate dehydrogenase complex suggested that the concentration ratio of NADH₂-NAD might be critical to a demonstration of effects of the concentration ratio of acetyl CoA-CoA on the kinase reaction.

This expectation has been realised in the present study in which pyruvate dehydrogenase kinase activity has been measured by the incorporation of ³²P into protein-bound phosphate from γ -³²P-ATP by an assay procedure described previously¹⁵. The only variation in the present study has been addition of effectors immediately before initiation of the reaction with γ -³²P-ATP. As shown by representative data in Table 1, NADH₂ activates the kinase reaction and NAD reverses the NADH₂ activation. In the presence of mixtures of NADH₂ and NAD, which themselves only partially activate, acetyl CoA activates the kinase reaction and CoA inhibits. Acetyl CoA reverses the inhibition by CoA provided sufficient NADH₂ is present. The pyruvate dehydrogenase kinase reaction is thus sensitive to concentration ratios of NADH₂-NAD and of acetyl CoA-CoA in a manner which may provide a basis for effects of fatty acids and ketone bodies also stimulates phosphorylation and inactivation of pyruvate dehydrogenase in perfused heart.

The mechanism of these complex effects of NADH₂, NAD, CoA and acetyl CoA is not known. In pyruvate dehydrogenase, E₂ forms the core of the molecule and carries E₁, E₃ and pyruvate dehydrogenase kinase¹⁷. If NADH₂, NAD, acetyl CoA and CoA affect the kinase reaction through binding to their substrate sites on E₂ and E₃, their effects must be transmitted from these subunits to the kinase or its substrate (E₁). One possibility is that lipoate might transmit these effects because it visits active sites on E₁, E₂ and E₃; the presence of oxidised lipoate on E₁ might inhibit phosphorylation of E₁ by the kinase so that when lipoate in one of its forms is located on E₂ or E₃ the kinase reaction could be facilitated. More conventional explanations for regulatory interactions between subunits involving either binding of the effectors to their substrate sites on E₂ and E₃ or to additional regulator sites on E₁ or the kinase may provide an alternative explanation for these effects of NADH₂, NAD, acetyl CoA and CoA.

Since this manuscript was submitted, Pettit *et al.*¹⁸ have reported inhibition of beef heart pyruvate dehydrogenase kinase reaction by CoA and by NAD, and activation of the kinase reaction by NADH₂ and by acetyl CoA. Our results with pig heart complex provide confirmation for inhibition by CoA and activation by NADH₂. We have not detected inhibition by NAD but rather reversal of NADH₂ activation by NAD. As mentioned earlier, we have not been able to detect significant activation of the kinase reaction by acetyl CoA except in the presence of mixtures of NAD plus NADH₂ which themselves produce no or only partial activation of the kinase reaction.

Pregnancy in the hyrax and erythrocyte metabolism of progesterone

HYRAXES are unusual for small mammals because they have a long gestation period (7.5 months) for their size (2-3 kg) and intra-abdominal testes^{1,2}. Hystricomorph rodents with long gestation periods relative to mature weight have a pregnancy-specific plasma protein with a high affinity for progesterone—progesterone-binding globulin (PBG). It occurs at high concentrations in the guinea pig and coypu, and evidently reduces the rate of progesterone clearance from blood³. We have found that, in the hyrax, the progesterone concentration in the corpus luteum is appreciable whereas that in plasma is low, and that erythrocytes metabolise progesterone *in vitro*. The results of this study are relevant to the phylogenetic affinity of the hyrax and elephant, and there is doubt about whether progesterone is the hormone of pregnancy in the elephant, since its concentration in the corpus luteum and peripheral plasma has been found to be very low⁴⁻⁷.

Steroid hormones of pregnancy were measured in the rock hyraxes, *Heterohyrax brucei* and *Procavia habessinica*, shot near Nairobi, and in captive *H. brucei*. Blood of shot specimens was taken into heparinised syringes and the ovaries and placentae removed immediately; all samples were transported to the

Fig. 1 The metabolism and uptake of ³H-progesterone by hyrax blood. Whole blood (0.5 ml) was incubated with ³H-progesterone, 0.5 μ Ci, 2.8 ng, at 4 °C (○) and 37 °C (●). Labelled progesterone was extracted from blood with 5 ml diethyl ether after the addition of 100 μ g unlabelled steroid to correct for procedural losses. After extraction, progesterone was separated by thin-layer chromatography (75:25, benzene-ethyl acetate), eluted with ethanol, and its specific activity determined by ultraviolet spectrophotometry and liquid scintillation spectrometry. The amount of labelled progesterone recovered was corrected for procedural losses and the result expressed as a percentage of added ³H-progesterone. The metabolism of ³H-progesterone at 4 °C was negligible and the apparent loss of steroid was related to red cell uptake. Enzymatic metabolism at 37 °C, however, was substantial.

Fig. 2 The metabolism of ^3H -progesterone by hyrax blood. Saline or whole blood (5 ml) was incubated with $2.5 \mu\text{Ci}$ ^3H -progesterone (14 ng) at 37°C for 3 h. After incubation, 1 ml 2.5% NaOH was added and each sample was extracted with 25 ml diethyl ether which was washed with distilled water and evaporated to dryness. The samples were applied to thin-layer chromatography plates and run for 15 cm in the solvent system, benzene-ethyl acetate, 4:6. a, ^3H -Progesterone added to saline, b, ^3H -progesterone added to hyrax blood; c, ^3H -compounds recovered from plate b acetylated at 70°C for 30 min. Chromatographic mobility of marker steroids indicated: (1) progesterone, (2) 5α -pregnane-3,20-dione; (3) 5β -pregnane-3,20-dione; (4) 20α -hydroxypregn-3-one; (5) 20β -hydroxypregn-3-one; (6) 3β -hydroxypregn-20-one; (7) 5β -pregnane-3 α ,20 α -diol (pregnenediol); (8) 5β -pregnane-3 α ,20 β -diol; (9) 5β -pregnane-3 β ,20 β -diol. Note the metabolism of ^3H -progesterone by hyrax blood (b) and the formation of compounds with chromatographic mobilities similar to those of 5α - and 5β -pregnenediol, and of hydroxylated pregnane metabolites with chromatographic properties similar to those of dihydroxypregnane compounds after acetylation.

progesterone (Table 1). In *Heterohyrax* the luteal concentration in pregnancy was $5.8\text{--}24.2 \text{ ng mg}^{-1}$, and one pregnant *Procavia* had 18.6 ng mg^{-1} . Progesterone concentration was low in one animal (J5, Table 1) but this did not seem to be associated with a failing pregnancy. A very low progesterone concentration was found in residual ovarian tissue after the removal of luteal tissue (less than 0.1 ng mg^{-1}) and in the placenta (less than 0.002 ng mg^{-1}).

An unusual feature of the hormone content of the hyrax corpus luteum was the high concentration of immunoreactive unconjugated oestrogens, $35\text{--}1,840 \text{ pg mg}^{-1}$ (Table 1). In contrast, the oestrogen concentration in residual ovarian tissue did not exceed 8 pg mg^{-1} , and in placental tissue it was less than 0.4 pg mg^{-1} .

Plasma concentrations of progesterone in blood taken by cardiac puncture were low in all females ($1.2 \pm 0.3 \text{ ng ml}^{-1}$, $n = 22$). In immature females the concentration was 0.3 and 0.4 ng ml^{-1} , in non-pregnant females, $0.6 \pm 0.2 \text{ ng ml}^{-1}$, and in pregnant females values ranged from less than 0.1 to 4.6 ng ml^{-1} during early, mid and late gestation. In hyrax J16 (Table 1), a mature female housed in laboratory conditions, the concentration in weekly samples varied between 1.5 and 3.8 ng ml^{-1} during approximately 30 d before a fertile mating. In early pregnancy, 4.6 ng ml^{-1} was recorded. The plasma progesterone concentration in males was $0.6 \pm 0.3 \text{ ng ml}^{-1}$ ($n = 8$).

The plasma concentration of unconjugated oestrogens in immature females was less than 10 pg ml^{-1} , in non-pregnant females 138 ± 19 ($n = 19$), and in pregnant females $106 \pm 44 \text{ pg ml}^{-1}$ ($n = 5$). The concentration in males, however, was of the same order, $134 \pm 35 \text{ pg ml}^{-1}$ ($n = 8$), indicating that reactivity was probably nonspecific.

Plasma samples from shot specimens contained a lower concentration of progesterone than those from captive animals obtained under anaesthesia. This loss of activity after sampling seemed to be related to a delay in separating the plasma from shot specimens. ^3H -progesterone incubated with whole blood at 37°C was metabolised (Fig. 1) to compounds corresponding in mobility to ring A saturated compounds less polar than progesterone, and hydroxylated steroids more polar than progesterone (Fig. 2). After incubation at 4°C only 62% of the ^3H -progesterone was recovered and the loss was associated with uptake by the red cells rather than enzymatic metabolism. Blood from shot specimens taken within 5 min of death and extracted immediately with diethyl ether gave progesterone values of 1.1 and 1.8 ng ml^{-1} (corrected for procedural losses) in two early-mid-pregnant females. These values were similar to those obtained in plasma from captive animals, and indicated that the amount of progesterone sequestered in erythrocytes was not large.

The amount of ^3H -progesterone recovered from hyrax blood after a 120-min incubation at 37°C was similar in non-pregnant and pregnant hyraxes (range $0.8\text{--}13.3\%$). The metabolism and uptake was attributable to erythrocytes since incubations with

laboratory at 4°C . Blood was taken from captive animals by cardiac puncture under chloroform anaesthesia. Plasma was separated by centrifugation within 15 min of collection from these animals, but at least 3 h elapsed before plasma could be obtained from shot specimens. Plasma and tissue samples were either extracted immediately or stored at -15°C . Progesterone and total unconjugated oestrogens were determined by radioimmunoassay (method A in ref. 8 and ref. 9). Tissue progesterone concentrations were corrected for procedural losses assessed by the recovery of a tracer amount of ^3H -progesterone added to each tissue. Details of these procedures will be published later.

The corpus luteum during pregnancy varied in wet weight between 13 and 18 mg and contained a significant amount of

an equivalent volume of red cells resulted in recoveries of only 11.0 and 12.0% of added ³H-progesterone. The rate of disappearance of ³H-progesterone was reduced if the erythrocytes had been lysed with distilled water; the average amount of labelled progesterone recovered being 41.1%. The enzymatic activity of erythrocytes with respect to ³H-progesterone was abolished by the addition of NaF.

The progesterone requirements of pregnancy may be met in various ways in different mammals¹⁰. In rats, sheep and women there is an increased production of progesterone; in guinea pigs there is a marked decrease in its rate of clearance and only a modest rise in production. The hyrax does not seem to fit either of these categories, since no evidence has been found of a high concentration of plasma progesterone in gestation, or of a pregnancy-specific plasma protein with a high affinity for progesterone.

The ability of erythrocytes to metabolise steroid hormones, including progesterone, has been reported in several species including man¹¹⁻¹⁵, but only in the foetal lamb, calf and kid has a rapid conversion of progesterone to 20 α -dihydroprogesterone been found^{14,15}. Although the two studies were not directly comparable, the rate of erythrocyte metabolism of progesterone *in vitro* seemed to be less in the hyrax than in the foetal lamb. In both species, however, cell lysis reduced enzymatic activity. In the hyrax, NaF, an inhibitor of anaerobic glycolysis, blocked progesterone metabolism which further supports the suggestion that steroid dehydrogenases in red cells utilise NADH generated by the glycolytic pathway¹².

A low plasma progesterone concentration during pregnancy has also been reported in the tammar wallaby¹⁶, but these marsupials have a gestation period of only 28 d. Maintenance of pregnancy by low plasma progesterone levels in the hyrax may be facilitated by a particularly sensitive receptor mechanism in the target tissues, with blood metabolism contributing to the protection of maternal and foetal tissues from any adverse effects of high hormone concentrations. There remains the controversial but interesting possibility that support of gestation in these animals depends on a metabolite, perhaps associated with erythrocyte metabolism of progesterone, rather than on progesterone itself. This possibility recalls work on the elephant which has cast doubt on the role of progesterone as the hormone of pregnancy⁷. Although the progesterone concentration in the corpus luteum of the hyrax contrasts with the low level reported in the elephant, the plasma levels in both animals are low during gestation. In neither animal does the endocrinology of pregnancy conform to patterns described in other mammals.

Pressure reversal of narcosis produced by anaesthetics, narcotics and tranquillisers

THE first demonstration of pressure reversal of anaesthesia in amphibians was provided by the tadpole experiments of Johnson and Flagler¹ with ethanol and ethyl carbamate. Since then the phenomenon has been studied using general anaesthetics in newts, mice and marine organisms^{2,3}, but few of these agents have been studied in detail and the results in some cases, for example, for barbiturates^{4,5}, are conflicting. Another aspect of the interaction of pressure and anaesthesia is the amelioration of the high pressure nervous syndrome by nitrous oxide, hydrogen or nitrogen⁶⁻⁸. It is not, however, known if other agents can also give 'pressure protection', and tadpoles provide a relatively easy model for a preliminary screening of potentially suitable drugs. We have studied both these aspects of the interaction between pressure and narcosis using intravenous, local and inhalational general anaesthetics and tranquillisers. We show that pressure reversal occurred with all our agents pro-

Fig. 1 *a*, Effect of pressure on tadpoles swimming in water equilibrated with different concentrations of halothane. ●, 0.005 atm; ○, 0.0075 atm; ■, 0.01 atm; □, 0.015 atm. Error bars indicate ± 1 s.e.m. calculated from five groups of five tadpoles. Dotted line shows effect of pressure alone. The tadpoles (*Rana temporaria*) were immersed in an aqueous solution of the agent at a known partial pressure and equilibrated for up to 30 min before pressurising to avoid any transitory effects associated with uptake and distribution of the agent. The chamber (400 ml capacity) was completely filled with solution which provided sufficient oxygen throughout the experimental period (up to 15 min). Pressure was applied using an oil-filled pump connected by way of a side chamber to prevent contamination. In almost all cases the observed effects were completely reversible, although recovery could take up to 18 h. *b*, Effect of pressure on tadpoles equilibrated with althesin—an intravenous steroid anaesthetic consisting of alphaxalone (3 parts by weight), alphadalone acetate (1 part by weight) in cremophor E. L. plus saline; (Cremophor E. L. was tested alone to ensure its inactivity). Concentrations were expressed as total steroid in $\mu\text{g ml}^{-1}$. ●, No anaesthetic present (dotted line); ○, 3.0 $\mu\text{g ml}^{-1}$; □, 4.2 $\mu\text{g ml}^{-1}$; ▽, 6.0 $\mu\text{g ml}^{-1}$. Error bars indicate ± 1 s.e.m. calculated from five groups of five tadpoles.

ducing narcosis in tadpoles, whereas pressure protection does not seem to be as universal.

Tadpole swimming activities in the presence of increased hydrostatic pressure with or without halothane or althesin are shown in Fig. 1*a* and *b*. It was only possible to quantify the response in terms of the presence or absence of movement (which was either spontaneous or initiated by tapping the side of the chamber). With pressure alone there was a progressive (but reversible) decrease in swimming activity—termed ‘pressure paralysis’—when the tadpoles became generally flaccid. In contrast to the inactivity produced by narcosis, however, pressure paralysis was normally accompanied by a pronounced bending of the tail. Other pressure effects included hyperactivity at 1,000–1,500 pound inch⁻² and tremors at 3,000–4,000 pound inch⁻².

The tadpoles were initially inactive in the presence of narcotics, but as the hydrostatic pressure increased they resumed swimming. The variation of narcotic reversal pressure with narcotic dose gives some indication of the differing degrees of pressure reversal. We found that the magnitude of the effect was too large to be attributed solely to the expected change of solubilities with pressure⁹. Decompression at the point of narcotic reversal produced an immediate return to narcosis which was again reversed by recompression. For both agents the effect of increasing the pressure was biphasic, although with althesin pressure paralysis only occurred above 5,000 pound

inch⁻². At the two highest halothane partial pressures the animals never fully recovered from narcosis before the onset of pressure paralysis.

Other agents were investigated using groups of five tadpoles and the results, expressed in terms of the onset of narcotic reversal and pressure paralysis at different doses of agents, are shown in Tables 1 and 2. The agents listed in Table 2 are not normally considered to be satisfactory general anaesthetics but, when the doses are sufficient to cause narcosis in tadpoles, pressure reversal can still occur. It has been postulated that benzocaine and procaine produce their local anaesthetic effects by membrane expansion, whereas agents such as lignocaine act at specific charged sites¹⁰. All three local anaesthetics however, had their narcotic effects reversed by pressure, which is consistent with the hypothesis that there is expansion of the critical site for narcosis independent of the agent.

Table 1 Narcotic reversal and pressure paralysis in tadpoles influenced by clinical anaesthetics

Agent	'Dose'	Complete narcotic reversal (atm)	Complete pressure paralysis (atm)

† These animals did not recover at the end of the experiment.

‡ Lethal – narcotising dose ratio close to unity.

Our results with ethanol are in agreement with those of Johnson and Flagler¹, who used different species of tadpoles and larvae. A high dose of morphine produced tadpole narcosis but there was no effect with two other narcotic analgesics, fentanyl citrate and pentazocine. The pressure reversal of the narcosis produced by the different tranquillisers emphasises that this phenomenon is not associated with specific agents or groups of drugs.

When studying the amelioration of the high pressure nervous syndrome we noted that tremors never occurred in the presence of narcotics, but since this effect was difficult to quantitate, we have not included it in our characterisation of ‘pressure protection’. With pressure alone, 100% activity is lost above 1,470 pound inch⁻², which is equivalent to 100 atm. Halothane seemed to give no significant protection against the paralyzing effects of high pressure (Fig. 1*a*); the animals exposed to 0.015 atm halothane died at 330 atm. In Tables 1 and 2 any figure for complete narcotic reversal above 100 atm indicates some degree of pressure protection. Several agents protected the tadpoles to some extent against the effects of very high pressure; these have a pressure paralysis value of > 300 atm. Althesin was the most successful agent that we used and is shown in Fig. 1*b*. This protective effect of althesin does not

Table 2 Narcotic reversal and pressure paralysis in tadpoles influenced by unconventional anaesthetics

seem to apply to all steroids; for example, hydrocortisone, a non-anaesthetic steroid, gave no pressure protection.

Our results demonstrate that the phenomenon of pressure reversal applies to narcosis in tadpoles regardless of the agent used. The compounds included a wide range of drugs with a very large variation in both anaesthetic potency and molecular size. These results may be relevant to the analogous situation in mammals since the ratio of tadpole narcotic concentration to the AD_{95} for surgical anaesthesia in man¹¹ is 2.75 ± 0.62 (s.d.), which has a coefficient of variation within that predicted by the accuracy of both measurements. Pressure reversal occurring with the steroids in althesin is particularly interesting because their anaesthetic activity in mammals seems to be related to their stereochemistry, and some workers have assumed that their mode of action is fundamentally different from the inhalational agents¹². Our data suggest that, although there may be some underlying minor differences in the physico-chemical basis of the expansion at the site of action, there are no intrinsic differences in the molecular mechanism of narcotic action of the inhalational and intravenous agents we studied.

We thank Mrs J. F. Nunn and the Misses Halsey for the sustained supply of tadpoles.

A leukaemic cell mutant with a thermolabile alanyl-transfer RNA synthetase

It may be of great help in the elucidation of regulatory systems in mammalian cells if we could isolate temperature-conditional mutants and identify their mutated functions. I report here that

a temperature-sensitive mutant of L5178Y murine leukaemic cells has a thermolabile L-alanyl-tRNA synthetase.

The *ts3* cells have been shown to exhibit a mutant character when grown in Fischer's medium but not in Ham's F12 medium, that is, cells grow at the non-permissive temperature (39 °C). L-alanine (10^{-4} M), hypoxanthine (3×10^{-5} M), and sodium pyruvate (10^{-3} M) are components of Ham's F12 medium but not Fischer's, and are responsible for growth of the mutant cells at the elevated temperature¹. Each of these substances was examined at various concentrations for growth stimulation.

Fig. 1 Effect of L-alanine on growth of *ts3* cells at 39 °C. 1×10^4 *ts3* cells ml^{-1} were inoculated in dialysed calf serum-containing Fischer's medium supplemented with various concentrations of L-alanine with (Δ) or without (○) hypoxanthine (3×10^{-5} M) and sodium pyruvate (10^{-3} M). After incubation at 39 °C for 3 d the cell numbers were scored.

For hypoxanthine and pyruvate the optimal concentrations were the same as those contained in Ham's F12 medium. Varying concentrations of alanine, however, exerted great influence on cell growth. As shown in Fig. 1, at 0.1 and 0.3 mM L-alanine, both hypoxanthine and pyruvate are required for *ts3* cells to grow at 39 °C. Above concentrations of 1 mM L-alanine, hypoxanthine and pyruvate are dispensable and alanine alone can support growth. No other L-amino acids, nor D-alanine, nor β-alanine could be substituted for L-alanine. Cell growth was inhibited at concentrations higher than 30 mM alanine. In the lower range of alanine concentrations pyruvate may serve as a precursor of alanine and be converted to the amino acid in the cell. Hypoxanthine has been shown to have a growth-promoting effect for L5178Y cells (T. Shiomu, personal communication).

Since *ts3* cells were shown to require alanine for growth at 39 °C, I examined the possibility that alanine biosynthesis was impaired at a restrictive temperature in the mutant. The main pathway of alanine synthesis is a conversion of pyruvate and L-glutamate to L-alanine and α-ketoglutarate and the reaction is carried out by alanine aminotransferase (EC 2.6.1.2). The enzyme activity was determined after exposing cell extracts to a high temperature². The initial specific activities expressed as μmol pyruvate formed per min per mg protein were 14.0 and 15.2 and the residual activities after 60 min at 40 °C were 11.6 and 12.8 for wild-type and *ts3* cells, respectively. This shows that the enzyme activity of *ts3* cells was as stable as that of parental wild-type cells at the elevated temperature, the residual activities being more than 80% for both wild-type and mutant cells. This result indicates that the main biosynthetic pathway of alanine is not altered in *ts3* cells.

The rates of incorporation of radioactive amino acids and

Fig. 2 Rates of incorporation of radioactive amino acids and nucleosides into acid-precipitable material after shift from 33 to 39 °C for *ts3* (○) and wild-type (Δ) cells. At the indicated times, cells were labelled for 30 min with either: a, ^{14}C -alanine (159 Ci mol^{-1} , $0.8 \mu\text{Ci ml}^{-1}$); b, ^{14}C -thymidine (49.5 Ci mol^{-1} , $0.1 \mu\text{Ci ml}^{-1}$); c, ^{14}C -valine (150 Ci mol^{-1} , $0.2 \mu\text{Ci ml}^{-1}$) or d, ^{14}C -uridine (59 Ci mol^{-1} , $0.01 \mu\text{Ci ml}^{-1}$). Ice-cold 5% TCA-insoluble material was collected on Whatman GF/F glass fibre filters, washed with TCA and ethanol, and counted in a toluene-based liquid scintillation counting fluid. Radioactive materials were purchased from Daiichi Pure Chemical Co., Ltd, Tokyo, and The Radiochemical Centre, Amersham.

nucleosides into acid-insoluble material were measured after shift from 33 to 39 °C for mutant and wild-type cells. As shown in Fig. 2, a steady reduction with time was observed in the rates of incorporation of alanine and thymidine in *ts3* cells, the level reaching 30% after 12 h (Fig. 2a and b), whereas the incorporation of valine and uridine did not change much during a 12-h period in mutant cells (Fig. 2c and d). It has been shown with *ts3* cells that leucine incorporation is unaffected for the first 24 h at the elevated temperature¹. Wild-type cells, by contrast, incorporated an increasing amount of all these precursors into macromolecules as the incubation time was prolonged (Fig. 2). Although the decline of thymidine uptake was observed in parallel with that of alanine uptake in mutant cells, this is not necessarily an indication that the DNA replicating machinery is also thermolabile. Since simultaneous protein synthesis is a requisite for DNA replication to initiate and continue in eukaryotic cells³, we could argue that the decreased synthesis of DNA results from the reduced incorporation of alanine provided that alanine is essential to the synthesis of the proteins required for DNA replication. The result that the incorporation of alanine, but not of leucine or valine, was affected at the restrictive temperature indicates that an alanine-specific process is modified in the mutant.

In bacteria many mutants auxotrophic for an amino acid contain an altered aminoacyl-tRNA synthetase⁴. Mutants with a temperature-sensitive alanyl-tRNA synthetase incorporate alanine at a decreasing rate but continue to incorporate leucine

Table 1 Thermal inactivation of aminoacyl-tRNA synthetases of wild-type and mutant *ts3* cells

^{14}C -amino acid	Residual activity (%) after 60 min incubation at 40 °C

pH 5.2 fractions were prepared from wild-type and mutant cells and exposed to 40 °C for 0 and 60 min. Aminoacyl-tRNA synthetase activities were assayed for each amino acid as described in Fig. 3.

at a constant linear rate after exposure to the high temperature⁵. These findings suggest the possible involvement of alanine-activating enzyme in *ts3* cells.

The thermal inactivation of L-alanyl-tRNA synthetase (EC 6.1.1.7) was examined. The "pH-5.2 fraction" was prepared⁶ from mutant and wild-type cell extracts and exposed to 40 °C for various lengths of time. The residual activity was measured at 30 °C for alanine and leucine (Fig. 3). The alanyl-tRNA synthetase from *ts3* cells was far more rapidly inactivated than that from wild-type cells at 40 °C (Fig. 3a), whereas the leucyl-tRNA synthetases from mutant and wild-type cells were

Fig. 3 Thermal inactivation of alanyl- and leucyl-tRNA synthetases of wild-type (Δ) and *ts3* (○) cells. From cell homogenates, pH 5.2 fractions were prepared⁶ and used for assaying alanyl- (a) and leucyl-tRNA synthetase (b) activities after incubation at 40 °C for indicated periods of time. Each 0.1 ml reaction mixture contains: 100 mM Tris-HCl (pH 7.5), 10 mM KCl, 4 mM magnesium acetate, 5 mM ATP, 2 mM dithiothreitol, 10 μM each of 20 L-amino acids, 2 mg ml⁻¹ rat liver tRNA (Grand Island Biological Co., Grand Island, New York), 15 μM ^{14}C -alanine (159 Ci mol^{-1}) or 15 μM ^{14}C -leucine (280 Ci mol^{-1}), and cell extract. Reactions were carried out at 30 °C for 15 min and terminated by the addition of ice-cold 10% TCA. Precipitates were collected on Whatman GF/F glass fibre filters, washed and counted.

inactivated at approximately the same rate (Fig. 3b). The residual activities of alanyl-tRNA synthetases after 60 min incubation at 40 °C were 5 and 78% and those of leucyl-tRNA synthetases were 20 and 29% for mutant and wild-type cell extracts, respectively. These results demonstrate that alanyl-tRNA synthetase activity of *ts3* cells is far more thermolabile than that of wild-type cells.

To determine whether the altered function is alanine specific, the heat stability of the other aminoacyl-tRNA synthetases was studied. As shown in Table 1, there is little difference in the residual activities between wild-type and mutant cell extracts for all amino acids except alanine. The result clearly shows that the elevated temperature inactivates each aminoacyl-tRNA synthetase from wild-type and mutant cells to approximately the same level with the exception of alanyl-tRNA synthetase.

The extreme lability of the alanyl-tRNA synthetase of the mutant in *in vitro* conditions will explain the temperature-sensitive growth character of *ts3* cells. Further purification of the enzyme will reveal whether the affinity for L-alanine or the recognition site for tRNA is altered as shown in bacterial mutants^{7,8}. A Chinese hamster ovary cell mutant with a temperature-sensitive leucyl-tRNA synthetase has been reported⁹. There is a striking difference between the leucine mutant and *ts3* cells; valine incorporation is affected in the former but not in the latter in the non-permissive condition. The continued valine incorporation in *ts3* cells may represent synthesis of proteins that are low in, or lack, alanine or of abnormal polypeptide derivatives⁵. Uridine incorporation into RNA does not change much with time in spite of the depletion in alanyl- or leucyl-tRNA, which may be accounted for by assuming that either the pool of uncharged tRNA has not reached a level sufficiently high to cause a general shut-off in transcription or the stringent control does not operate in high eukaryotes. A decline in DNA synthesis is observed in both mutants and explained as a secondary consequence of reduced synthesis of initiator proteins of DNA replication. These points are, however, to be substantiated.

Non-conditional alanine-requiring mutants have been described¹⁰ which may carry a similar mutation.

I thank Dr P. Newmark and the referee for helpful comments, Drs A. Matsushiro and Y. Takeda for discussions, and Mr I. R. Moore for critical reading of the manuscript. This work was supported by the Japanese Ministry of Education.

three of these head proteins are found intact in the phage; the products of genes *E* and *D*, pE and pD, form the outer shell of the capsid⁶, and pF_{II} is thought to form part of the head-tail connector⁷. The other two gene products pB and pC undergo extensive alterations during head assembly. pC is fused to a minor fraction of pE and is cleaved to form two polypeptides, X1 and X2, which differ only in the length of the pC fragment present⁸. There are between three and nine molecules of each of these proteins in the phage head⁶. The product of gene *B*, pB, is also cleaved during head assembly to form pB* (refs 4–6). There are between 10 and 14 molecules of pB* in the phage^{3,6}. Since an icosahedron has 12 corners, it has been suggested that 12 pB* molecules are structural components of the corners of the viral capsid^{9,11}.

We suggest, however, that the pB* molecules are not distributed in the corners of the icosahedral viral shell but that, together with X1 and X2, they form the collar structure which connects the head and the tail. We have based these conclusions on the following observations. Petit λ particles (pλ), which appear in electron micrographs to be less angular in outline, and about three-quarters the diameter of λ heads (Fig. 1)¹², are normal precursors of mature λ heads^{11,12,24,25}. Particles similar in appearance, although not able to act as head precursors, can be obtained in equivalent amounts in the absence of pB and pC (refs 11, 14 and 15). According to the general principles regulating the construction of isometric viral shells, elaborated by Caspar and Klug, pλ particles must have 12 corners¹⁶. Therefore the presence of structures like pλ in B[−] and C[−] lysates indicates that pB and pC are not essential for the formation of corners. The less angular outline of all pλ relative to λ can be explained simply in terms of the grouping the major structural proteins pE and pD on the surfaces of pλ and the mature head capsids as follows. In pλ, 420 molecules of pE are thought to be grouped as hexamers and pentamers to give 72 morphological capsomers^{17,24}. During maturation of the proheads, however, the pE molecules are regrouped as trimers and 420 molecules of pD are added to the shell, grouped as hexamers and pentamers, yielding a total of 212 capsomers one-half the size of the pE-containing pλ capsomers^{17,18,24}. The decrease in size and the increase in the total number of capsomers in λ heads could explain the observation that mature phage heads are more angular than pλ.

The collar structure observed in electron micrographs of λ heads (Fig. 1) is presumably derived from the head, since tails acquire collars only after their attachment to heads^{11,19–22}. Furthermore, it is likely that the collar is a preformed head structure and not simply a rearrangement of capsid proteins in response to the addition of a tail. Harrison and Bode (cited in ref. 21) have argued that such major structural alterations are unlikely in view of the low activation energy of head-tail joining reaction *in vitro* (8.5 kcalorie mol^{−1}).

A rough estimate of the size of the collar structure based on measurements from the electron micrograph in Fig. 1b gives a molecular weight of 1 × 10⁶. Thus, the five or six molecules of pF_{II} (molecular weight 12,000) present per phage⁷ could not make up the bulk of the material seen in electron micrographs (Fig. 1b). Furthermore a collar-like structure can be seen in phage heads and in pλ in F_{II}[−] mutant lysates (Fig. 1g). Clearly this structure must contain other head proteins in addition to the five to six molecules of pF_{II}.

The presence or absence of a collar-like structure in empty heads and in proheads can be correlated with the presence or absence of pB*, X1 and X2 based on examination of the structures found in lysates of phage mutants. Empty heads found in lysates of a *Vam* tail defective mutant (Fig. 1c) have a structure which appears under the electron microscope to be very similar to the tail-collar

Model for arrangement of minor structural proteins in head of bacteriophage λ

THE morphogenesis and maturation of the head of bacteriophage λ requires the function of 10 phage genes^{1–5}, with the products of five of these genes, *E*, *D*, *F*_{II}, *B* and *C*, present as structural components of the head^{4,6,7}. The first

Fig. 1 Presence of tail collar in phage and pλ. Typical structures found in lysates with collar structures indicated by arrows. *a*, Lysate obtained after induction of 594(λ Cl₈₅₇Sam₇) showing a complete DNA-filled phage particle and a pλ with a collar. *b*, Ghosted phage showing collar joining tail to head. *c*, Empty heads from a lysate of 594(λ Cl₈₅₇Vam₇₅₀Sam₇). *d-g*, pλ with collar from lysates of induced cultures of: *d*, 594(λ Cl₈₅₇Aam₃₂₇Sam₇); *e*, 594(λ Cl₈₅₇Dam₁₅Sam₇); *f*, 594(λ Cl₈₅₇F₁₁am₇₈₅); *g*, 594(λ Cl₈₅₇F₁₁am₄₂₃Sam₇). A collar structure was clearly visible in about 30–50% of the pλ in the above lysates. *h-k*, pλ showing the absence of the collar, from lysates of induced cultures of: *h*, 594(λ Cl₈₅₇Bam₁₀Sam₇); *i*, 594(λ Cl₈₅₇Cam₄₂Sam₇); *j*, 594(λ Cl₈₅₇Bam₁₁Cam₄₂Sam₇); and *k*, 594(λ Cl₈₅₇Nu3am₈₈Sam₇). For a more complete description of the strains used, see refs 14 and 23. The preparation of the lysates and the procedures used for electron microscopy were described previously²³. *a-b*, $\times 160,000$; *c*, $\times 120,000$; *d-k*, $\times 100,000$.

found in disrupted phage heads (Fig. 1*b*). This structure is also found in pλ from wild-type lysates and from lysates of A^- , D^- , F_I^- and F_{II}^- phage-infected cells (Fig. 1*a* and *d-g*). Polyacrylamide gel electrophoretic analysis has indicated that all of these types of pλ particles contain pE, pB*, X1 and X2 (refs 9, 11 and 23). The collar-like structure is not found in pλ which do not contain pB*, X1 or X2, that is, pλ from lysates of B^- , C^- , B^-C^- or $Nu3^-$ phage-infected cells (Fig. 1*h-k*). Lysates of λC^- -infected cells contain three morphologically distinct pλ (Fig. 1*i*). Some appear completely empty, some appear completely full, and some have a small inclusion which is similar to the collar structure seen in wild-type proheads (Fig. 1*a*). In C^- pλ, however, this inclusion is larger and more diffuse than wild-type pλ collars, and may be unprocessed pB or pNu3 which has been found in these pλ (refs 9, 11 and 23). Since pE forms the outer shell of the pλ particle and is found in all types of pλ, regardless of whether they contain the collar-like

structure^{9,11,23}, it seems likely that the structure seen in Fig. 1*a-g* is made up of pB*, X1 and X2, rather than pE.

Previous data²³ suggest that pB and pC interact, and that the cleavage of pB requires the previous cleavage of pC. Thus it seems more likely that these proteins share a common function in the prohead, rather than being dispersed over the capsid.

These observations suggest that pB*, X1 and X2 form part of the head-tail connector. Figure 2 shows a model to explain how these molecules might be attached to a single corner of the head. The model proposes that the cleavage and fusion of pC and pE to form X1 and X2 takes place at only one of the 12 corners of the icosahedral shell.

Figure 2*a* shows a flat lattice structure of pE molecules grouped as hexamers as has been suggested for the molecular arrangement of the pλ capsid^{17,24}. Superimposed on this lattice is the outline of one face of the icosahedral structure. A corner can be generated from this planar hexagonal net with minimum distortion of the bond angles by cutting along one of the sides of the icosahedral face (Fig. 2*a*, broken lines) and folding the net into a cone to convert the corner capsomer to a pentamer¹⁶. The corner thus generated (Fig. 2*b*) consists of a pentamer of pE surrounded by five pE hexamers. The five faces of the icosahedron forming this corner are indicated by broken lines in Fig. 2*b*. If the pE pentamer is removed from this corner the resulting hole is surrounded by 10 molecules of pE (Fig. 2*c*, cross hatching). These 10 molecules of pE are not in identical molecular environments, but rather form two groups. One group, the even-numbered molecules in the figure, is oriented such that the left side of each molecule is facing the centre of the corner. The odd-numbered molecules have their right side facing the centre of the corner. We propose that 10 pC molecules are fused to these 10 pE molecules and are subsequently cleaved to form five molecules of X1 and five of X2 (Fig. 2*d*). The different molecular environments of the pE molecules could explain the presence of two sets of molecular species, X1 and X2, which have the same amino acid sequence but differ only slightly in length⁸. Ten molecules of pB* would then be located in contact with the ten X molecules to form the collar (Fig. 2*e*) seen in Fig. 1*d-g*.

Our previous results²³ suggest that pNu3 is involved in the assembly and functional cleavage of pB and pC. pNu3 has not been included in the model (Fig. 2) primarily because

Fig. 2 Model for the arrangement of the minor structural proteins of the head, pB*, X1 and X2, in the collar structure. See text for details.

it has a transient role in assembly and is not a structural component of the mature virion. It is possible that pNu3 provides a substructure to which pB and pC bind to form a precollar structure. This structure could then function as a prime corner which may serve as an initiation point directing the addition of pE to give a complete pλ. The processing of pB and pC would then produce the collar. This model would then provide a mechanism which would prevent pλ from developing more than one collar which might render them inactive in further head assembly. It might also provide an explanation for the formation of monsters in B⁻, C⁻ and Nu3⁻ lysates, which could be produced by the non-directed assembly of pE occurring in the absence of the pre-collar structure. B⁻, C⁻ and Nu3⁻ lysates contain large numbers of pλ; a prime corner is therefore not essential for pλ formation although it may be required for functional pλ assembly as the pλ isolated from these lysates do not act as preheads in the *in vitro* DNA packaging assay¹¹. There are insufficient data available to determine whether collars nucleate the assembly of pE or whether they are added to pre-existing pλ.

¹⁵N nuclear magnetic resonance of living cells

DIRECT observation of nuclear magnetic resonance (NMR) signals in living tissues, cells, or in their particulate components is an appealing aspect of NMR spectroscopy as it further extends its applicability from the chemical to the biological domain. Of the various nuclei available for NMR studies, ¹H (refs 1-3), ¹³C (refs 2 and 4) and ³¹P (ref. 5) have already been observed in complex biological systems. The potential of the technique for the study of dynamic metabolic processes, or, eventually, aspects of cellular physiological changes, has been demonstrated^{6,7}. No other spectroscopy affords the resolution and direct interpretability in terms of chemical functional groups that NMR provides. One drawback is its relative insensitivity, especially when the representative nuclides of biological interest occur in low natural abundance, for example, ¹³C, ¹⁵N. In the case of ¹³C, isotopic enrichment from suitably labelled precursors has been shown to provide most valuable

metabolic data in whole cell investigations⁸. There seem however, to be no studies of this type using nitrogen NMR. The relevance of nitrogen as a fundamental element of the constitutive building blocks of lipids, nucleic acids, proteins, and even some sugars, suggests that its direct observability in cells should provide an important probe to monitor the dynamics and control of its *in vivo* fixation and metabolism. We report here some results showing that ¹⁵N-NMR signals can be directly observed in whole, living cells.

The fungus *Ustilago spheerogena* was grown at 30 °C in the low-iron media⁹ in which 95% ¹⁵N-ammonium acetate (Merck, Sharp and Dohme, Canada) was used as the sole nitrogen source⁹. Iron starvation, resulting in slow cell growth, was required to stimulate the production of ¹⁵N-enriched ferri-chrome peptides which are the subject of additional ¹⁵N-NMR investigations. The cells were collected and concentrated by centrifugation on day 17 after inoculation. Such cells are perfectly healthy as they can be routinely used as inoculum to start growth of new cultures. From 3.3 l culture medium the

Fig. 1 ¹H-noise decoupled Fourier transform ¹⁵N-NMR spectra at 10.1 MHz of an ¹⁵N-enriched culture of *U. spheerogena*. a, Culture medium free of cells; b, freshly collected cell slurry; c, cell slurry aged for 9 d at 3 °C, and washed with distilled water before the NMR measurement. Spectra were taken at 32 °C on a Varian XL100-15 spectrometer. The chemical shift scale (p.p.m.) is referred to the external ¹⁵NO₃⁻ resonance measured in a separate tube containing a solution of 0.5 g ¹⁵NH₄⁺¹⁵NO₃ in 3 ml D₂O/H₂O (Varian ¹⁵N standard 920 350-57). Each spectrum represents 120,000 pulse repetitions.

total yield of cells was a tightly packed pellet of about 10 ml. This material was divided into several batches, and both the cell pellets obtained by centrifugation and the growth medium were investigated using NMR.

In a first experiment about 2.8 ml of the packed cell slurry were deposited in a 12-mm NMR tube immediately after collection. A proton noise-decoupled ^{15}N -NMR spectrum of such a sample shows a group of four distinct resonances at -249.8 p.p.m., -253.8 p.p.m., -256.2 p.p.m. and -261.9 p.p.m., the amplitude of the signal at -253.8 p.p.m. being about ten times larger than that of the other resonances (Fig. 1b). No other resonances were observed in the spectral region from 30 to -470 p.p.m. To check for the possibility that some or all of the signals could arise from ^{15}N -labelled metabolites present in the growth medium external to the cell, a spectrum of the supernatant medium was recorded in the same conditions (Fig. 1a). A single signal was detected at -280.9 p.p.m., that is 19 p.p.m. more than the highest field signal arising from the cell pellet shown in Fig. 1b. This shows unequivocally that the signals in Fig. 1b arise from compounds within the cell.

In a second experiment, another batch of about 3 ml of the packed cell slurry was resuspended in the culture medium, and kept at 3°C for 9 d after collection. Thereafter the cells were separated by centrifugation, resuspended in distilled water, and left overnight at 10°C with continuous stirring. The cells were then centrifuged and transferred to an NMR tube as described above. The spectrum of such cold-aged, washed cells is shown in Fig. 1c. Only one signal was observed at -260.9 p.p.m., showing that at least three components present in the freshly collected cells (spectrum b) diffused out or were metabolised during the ageing period. Direct evidence for a metabolic inter-conversion comes from the observation that the strong line in spectrum c is in a spectral range which contained only a weak line in the freshly collected cells. Within the accuracy of the chemical shift determination it may well be that the signal in spectrum c and the line at -261.9 p.p.m. in spectrum b correspond to the same compound. Observation of resonances at 251.9 p.p.m., in the range of 145 – 155 p.p.m., and at 51.6 p.p.m. in the aqueous extract showed, on the other hand, that ^{15}N -metabolites leaked out during the wash.

At this stage the question arises as to the origin of the observed resonances. Overall, the frequency region in which the resonances are observed is typical for peptidyl amides. For example, the glycylglycine amide resonance is at -258.5 p.p.m. in the range $4 < \text{pH} < 10$, (ref. 10) and for a variety of other dipeptides and polypeptides the ^{15}N chemical shift typically varies from -270 to -230 p.p.m.¹¹. On the other hand, from chemical shift considerations the following representative compounds may be excluded: free amino acids (-290 to -350 p.p.m., excluding the ring nitrogens of histidine and tryptophan)¹¹, NH_4^+ (-354 p.p.m.)¹², $(\text{H}_2\text{N})_2\text{C}=\text{O}$ (~ -300 p.p.m.)¹³. The *Ustilago* ^{15}N signals are narrower and better defined than the resonances observed by Lapidot *et al.*¹⁰ in ^{15}N -labelled haemoglobin, which seems to be the only protein whose ^{15}N spectrum has been reported. Low molecular weight peptides exhibit relatively narrow ^{15}N resonances as exemplified by the natural abundance ^{15}N -NMR spectra of Viomycin and gramicidin S, a cyclopenta- and a cyclodecapeptide, respectively¹¹. The resonances shown in spectra b and c may thus quite likely arise from the low molecular weight peptide pool of the cell, intermediate in protein and peptide synthesis. In the growth conditions used here, *U. sphaerogena* is an active producer of the ferrichrome cyclohexapeptides, which contain a triornithyl sequence¹⁴. This suggests that the cells possess an active nitrogen metabolism in the region of the urea cycle so that it is not surprising that small ^{15}N -labelled metabolites should occur in sizeable concentrations.

The present study definitely establishes the suitability of ^{15}N -NMR as a non destructive tool for studying aspects of the cellular nitrogen metabolism, especially so since isotopic effects of ^{15}N , *vis-à-vis* the most abundant ^{14}N isotope, ought to be negligible. As with ^{13}C -NMR, improved instrumentation

and increased availability of labelled compounds should further enhance the appeal of ^{15}N -NMR for biochemical studies.

We thank Professor R. Hütter (Mikrobiologisches Institut der ETH) for the use of laboratory facilities, and Schweizerischer Nationalfonds for financial support.

Quaternary and tertiary structure of haemerythrin

THE oligomeric protein haemerythrin is an oxygen-transport pigment found in erythrocytes of the coelomic fluid of certain invertebrates. It usually occurs as an octamer of molecular weight 108,000, in which each subunit contains two Fe atoms and reversibly binds one O_2 molecule¹. There is convincing evidence that myohaemerythrin, a monomeric protein found in the retractor muscles of the sipunculan worm *Themiste pyroides*, and the protomers of haemerythrin have quite similar tertiary structures^{2,3}. Consequently, the low resolution structure obtained for myohaemerythrin⁴ has been used to solve the structure of octameric haemerythrin by molecular search techniques.

Haemerythrin from the sipunculan *Phascolopsis* (syn. *Goldfingia*) *gouldii*⁵ is a hybrid molecule comprising five molecular variants, four of type A and one of type B, which differ only slightly in primary structure. Metazide-haemerythrin was dissociated and haemerythrin B monomers were isolated as described previously⁶. After purification by rechromatography, the monomers were reacted with excess cysteine ethyl ester to reconstitute octameric haemerythrin B (ref. 7). The protein was purified on Sephadex G-75 and concentrated by pressure ultrafiltration to give a 30 mg ml^{-1} solution. Tetragonal crystals were grown in sealed drops containing $5\text{ }\mu\text{l}$ of this solution and $2\text{ }\mu\text{l}$ of 2-methyl-2,4-pentandiol. The diffraction pattern from these crystals has Laue symmetry $4/\text{mmm}$ with reflections $00l$ extinct for odd l . The lattice constants measure $a=b=104.82\text{ }\text{\AA}$ and $c=54.08\text{ }\text{\AA}$. A more detailed description of the preparation of reconstituted octameric haemerythrin and of crystals grown from this material will be presented elsewhere.

The unit cell volume relative to the molecular volume of haemerythrin indicated that there must be two molecules

Fig. 1 Stereoplots of isolated electron density distributions (a) for a myohaemerythrin molecule and (b) for a haemerythrin protomer. The orientation for each corresponds to that of subunit 1 of Fig. 2. The myohaemerythrin map is a rotated version of one presented earlier⁴. The haemerythrin map is based on phases derived initially from the myohaemerythrin model and improved by a process involving the averaging of electron density related by non-crystallographic symmetry and the constraining of density in solvent regions to a constant level. The first contour level is at $0.53 \text{ e } \text{\AA}^{-3}$ for myohaemerythrin and at $0.51 \text{ e } \text{\AA}^{-3}$ for haemerythrin. Higher contours are drawn at intervals of $0.20 \text{ e } \text{\AA}^{-3}$. Density values are on a quasi-absolute scale and include the F_{000} contribution. Although these density distributions for myohaemerythrin and haemerythrin are similar, significant differences are evident. The most pronounced structural difference appears at the CD corner and must reflect the five residue deletion in this region of haemerythrin compared with myohaemerythrin. The increased density near the beginning of helix C in haemerythrin may represent the bulkier side chains of residues (Glu, Phe, Tyr, Asp) which replace myohaemerythrin residues (Ser, Glu, Val, Val) at positions 68–71 (G. L. K., J. L., Cote, and S. E. Ludlam, unpublished). On the other hand, apparent differences at the start of the A helix may only be due to excess density from a close lattice contact in the myohaemerythrin crystal. It is interesting that the density appended at the first bend in the N-terminal arm, which decreased during the course of myohaemerythrin refinement, is much reduced in haemerythrin. These and other seemingly significant differences in the two maps indicate that the bias towards myohaemerythrin in the initial phase information for haemerythrin has been largely overcome.

in the unit cell to give a solvent content in the range typical of protein crystals⁸. Placements of two molecules in space group $P4_222$ are incompatible with the molecular symmetry and dimensions suggested by previous studies of haemerythrin crystals^{9,10}. Instead, the data are readily explained by two octamers centred about the special positions $(0, 0, 0)$ and $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$ in space group $P422$. Since the cell is not centred, the two molecules must differ in orientation by a 45° rotation about the c direction. Pseudo eightfold symmetry observed in $hk0$ precession photographs is consistent with this view. Exact 422 (D_4) symmetry of haemerythrin B is therefore revealed by this elegant arrangement which, in addition, uniquely defines the relative disposition of the two protomers in the asymmetric unit.

X-ray diffraction data from $\text{CuK}\alpha$ radiation were collected using a diffractometer to 5.5 \AA resolution and corrected for absorption and the L_p factor. Initial phases for the observed structure amplitudes were calculated by Fourier inversion of a model structure composed from the electron density of isolated myohaemerythrin molecules appropriately oriented and positioned. An approximate orientation was determined by using the fast rotation function of Crowther¹¹ to correlate the observed intensity data with the squared transform of the electron density distribution in an isolated myohaemerythrin molecule. Attempts to ascertain the position using a translation function¹² were unsuccessful. Fortunately, a packing analysis limited the possible translational positions to three unique regions in the cell. Structure factors calculated from reoriented

myohaemerythrin molecules positioned at one of these possibilities satisfactorily matched the observed 20-\AA resolution data. This model was then improved by trial and error adjustment of the rotation and translation parameters in order to reduce the conventional R factor for data to 8-\AA resolution. Finally, the parameters were refined by a succession of fittings of the myohaemerythrin density to 5.5-\AA resolution Fourier maps of haemerythrin B based on phases from the current model. Details of the structure analysis will be presented elsewhere.

Several factors affirm the correctness of this structure solution. The final model structure gives an R value of 0.43 for all $1,141$ data. Packing contacts between subunits in this structure are stereochemically reasonable (Table 1) and consistent with biochemical evidence on possible subunit interfaces. Further credence is lent to the proposed structure by the strong density returned at expected iron sites in a Fourier synthesis of haemerythrin based on phases calculated from a myohaemerythrin model from which density for the dimeric iron centre had been removed. Also, the iron atoms of myohaemerythrin transform to positions close to multiples of $c/16$ which explains the great intensity of reflection $(0, 0, 16)$. Finally, Fig. 1 illustrates that the major differences in tertiary structures seen between these images of haemerythrin and myohaemerythrin correlate with the known differences in primary structure⁴.

The eight subunits of *P. gouldii* haemerythrin B are associated in 422 symmetry to form a molecule having approximate external dimensions of $75 \times 75 \times 50 \text{ \AA}$. The

quaternary structure is illustrated in Fig. 2. Each subunit is oriented with its long (pseudo-diad) axis roughly perpendicular to the fourfold rotation axis (R). The assembly consists of two layers, each a square comprising four protomers related by R in an end-side arrangement. Layers are related to one another by the four twofold axes ($P1$, $Q1$, $P2$, $Q2$) which lie normal to R in a plane between layers. This formation produces a channel along R which swells to a chamber in the centre of the molecule. The chamber is 30 Å in diameter and 15 Å high and is bounded

Fig. 2 Quaternary structure of haemerythrin B. Axes in a molecular coordinate frame are designated by $P1$, $Q1$, $Q2$ and R . For the molecule shown, diads $P1$ and $P2$ and the tetrad R are parallel to x , y and z , respectively, and intersect at $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$ of the crystallographic system. Subunits are drawn as schematic representations of the polypeptide chain. The amino-terminal arm is designated by N and helical segments are labelled $A-E$ in accordance with the notation for myohaemerythrin⁴. The dimeric iron centres are represented by the oblate spheroids on which subunit numbers appear. Subunits 1-4 are numbered anticlockwise about R starting from protomer 1 in the third quadrant of the lower layer. Subunits 5-8 are related respectively to 1-4 by diad $P1$. Subunit 1 as viewed in a corresponds to the electron density distribution of the haemerythrin protomer shown in Fig. 1. View a is along R and shows the four protomers (stippled) in the lower layer and two of the four upper layer protomers (hatched) related by diads P and Q to the former. View b shows four subunits, two from each layer, as seen from within the octamer along the diad $P1$. Figures drawn from computer-generated schematics.

Table 1 Subunit interfaces within and between octamers

Subunit pair and symmetry	Structural features with potential for contact	C_{α} pairs within 10 Å
R (1 \rightarrow 2)	BC (63-66) \rightarrow B (45-46, 48-50, 52-53, 56-57) BC (64-65) \rightarrow C (77, 81) E (107-108, 111-113) \rightarrow B (42, 45-46, 49-50, 53)	42
R (4 \leftarrow 1)	Reciprocal to R (1 \rightarrow 2)	42
$P2$ (1 \rightleftharpoons 7)	N, A (17-19) \rightleftharpoons N, A (17-19) N, A (17-20) \rightleftharpoons E (111-113)	22
$Q1$ (1 \rightleftharpoons 8)	N (8-12) \rightleftharpoons A (27, 30-31, 33-34, 38) N (11-12) \rightleftharpoons B (43, 46) A (19-20, 23) \rightleftharpoons B (46, 50) A (22-24, 26-27, 30-31) \rightleftharpoons A (22-24, 26-27, 30-31)	71
1 \rightleftharpoons 8' ($\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$)	C (75, 78) \rightleftharpoons C (75, 78)	3
1 \rightarrow 6'' (0, 0, 0)	A, AB, B (36-41) \rightarrow N (1-3) CD (87-88) \rightarrow N (1-2) CD (87-88) \rightarrow D, E (103, 106)	15
1 \rightarrow 7'' (0, 0, 0)	N (1-3, 5) \rightarrow A, AB, B (38-41)	7

All of the subunit interactions encountered by one protomer from the octamer centred at $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$ are tabulated here. These include four intramolecular contacts due to symmetry operations of the diads, P and Q , and the fourfold axis, R , and three intermolecular lattice contacts with subunits of the other independent octamer. The specific subunits and symmetry operators designated in this table refer to those identified in Fig. 2. Subunit 8' is related to 8 by a unit translation in z and subunits 6'' and 7'' are related to 6 and 7 by a 45° anticlockwise rotation about $(\frac{1}{2}, \frac{1}{2}, z)$ and translation by $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$. The contacts made by a protomer from an octamer at (0, 0, 0) are identical to those of one at $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$ except for lattice contacts reciprocal to those cited as 1 \rightarrow 6'' and 1 \rightarrow 7'' above. Structural features are designated by helix and corner letters⁴ in the notation of Fig. 2 with sequence positions⁶ of specific residues in parentheses. The identification of residues with potential for intersubunit contact was made by noting pairs of C_{α} atoms from different subunits which lie within 10 Å of each other. The C_{α} positions were derived from a tentative model¹⁴ for the polypeptide backbone of this protein. Those C_{α} atoms (25, 28, 29, 35, 43, 47, 51, 54, 55, and 62) which met the 10 Å criterion for potential contact but which were shielded by more superficial residues were excluded in this tabulation. The resulting number of non-shielded intersubunit C_{α} pairs within 10 Å of one another is given in the third column for each interface. The closest approach of an intersubunit C_{α} pair is 4.1 Å within a molecule and also 4.1 Å between molecules. The closest approaches between C_{α} atoms of protomer 1 and those of 3, 5, and 6 are 18.4, 26.4 and 25.1 Å, respectively.

by helices A and B and the E helical stub. The channel is lined by B and C helices and has a limiting aperture 20 Å square. Other access to the central chamber may be possible through eight small openings alongside the *P* axes (Fig. 2b).

Of the six possible types of subunit interactions in an oligomer with 422 symmetry¹³, three occur in haemerythrin. One type is the heterologous association between adjacent protomers related by *R* in a layer. Each subunit participates in two such interactions. The major isologous interaction is that between neighbouring protomers related by *Q* axes. Less extensive interaction exists between adjacent protomers related by *P* axes. The subunit interfaces in these associations are characterised in Table 1 by reference to a tentative model¹⁴ for the polypeptide backbone of haemerythrin. Several studies have implicated the involvement of certain residues at subunit interfaces^{7,15-19}. In agreement, this model has Cys-50 located near both the *Q* and *R* interfaces, and has Tyr-18, His-34, four lysines, and several carboxylates also placed at contact surfaces. In contrast, Tyr-70 and the variable residues^{6,20}, with the exception of Glu-63 and Val-9, do not occur near subunit contacts. The relative importance of the *P*, *Q* and *R* interfaces in stabilising the octamer is suggested by the contact ratio 22:71:84. Moreover, since the ratio of intramolecular contacts to lattice contacts is 177:25, the molecular structure is probably little affected by lattice interactions; thus averaging of crystallographically-independent subunits is justifiable at this stage of refinement. A more detailed description of the structure will be presented elsewhere.

Before completion of this investigation, we were informed that the structure of *Themiste dyscritum* haemerythrin had been solved by a single isomorphous replacement. While this manuscript was in preparation, we received a preprint²¹ describing those results. The two independent analyses have revealed essentially identical structures.

We thank Dr J. Karle for his interest and support, and Diane Ward for her illustrations. K.B.W. was supported by an NRC research associateship.

Functional equivalence of the two iron-binding sites of human transferrin

FLETCHER and Huehns^{1,2} presented evidence that the two iron atoms bound to the serum iron-transport protein, transferrin are not equally available for the synthesis of haemoglobin by immature red blood cells (reticulocytes). They hypothesised that functional differences between the binding sites may serve to regulate the distribution of iron within the body³. Various studies (cited in ref. 4) have been published since, some of which support and some of which contradict this hypothesis. We devised procedures⁴ to compare the availability of iron at each site of transferrin for reticulocytes *in vitro*, as well as to compare the availability of iron in diferric and monoferric transferrin. In the homologous system of rabbit reticulocytes and rabbit transferrin, there was no functional difference between the two sites of diferric transferrin or between diferric and monoferric protein. In the heterologous system of rabbit reticulocytes and human transferrin, however, a difference between the sites of diferric transferrin and between diferric

Fig. 1 Ratio of the uptake of ⁵⁹Fe and ⁵⁵Fe in double incubation experiments. *a* and *b*, Human cells plus human protein; *c* and *d*, rabbit cells plus human protein. To increase the fraction of iron consumed, the concentration of transferrin in experiments with human reticulocytes was 1-3 that used previously in experiments with rabbit reticulocytes⁴. Haematocrits in incubation mixtures ranged from 25 to 50%. In the first incubation the ⁵⁹Fe consumed was: *a*, 20%; *b*, 59%; *c*, 22%; *d*, 39%; *e*, 25%; *f*, 46%. In experiment *a* blood from a patient with thalassaemia intermedia was used in the first incubation, and from a patient with haemoglobin C disease in the second. In experiment *b* each incubation made use of blood from different patients with sickle cell anaemia. The reticulocyte counts in the human blood ranged from 9 to 18%. Total incubation times in the second experiment were *a*, 120; *b*, 150; *c*, 35; *d*, 22; *e*, 60; and *f*, 32 min. In experiments *e-f* the incubation medium contained bovine serum albumin at a concentration of 2 mg ml⁻¹ before addition of cells. In experiments *a* and *b* albumin was omitted. Experiments *c* and *e* come from ref. 4.

and monoferric transferrin was observed. Those studies have now been extended to the homologous system of human reticulocytes and human transferrin. We found no difference in availability of iron at the two sites of human transferrin and only a slight difference in the availability of iron in monoferric and diferric protein.

To assess the relative availability of iron at the two binding sites, the following procedure was used⁴. Transferrin was treated with a quantity of ^{59}Fe -nitrilotriacetate sufficient to saturate 115% of the specific binding sites, and the excess iron was removed by gel filtration through Sephadex G-25 equilibrated with the saline incubation medium. After adding glucose to a concentration of 1 mg ml^{-1} , the ^{59}Fe -saturated protein solution was incubated with reticulocytes until 20–59% of the iron had been consumed by the cells. A quantity of ^{59}Fe -nitrilotriacetate calculated to be 10% in excess of that needed to replace consumed ^{59}Fe was then added to the supernatant incubation solution. After standing for 30 min at 20°C and 30 min and 37°C , the solution was passed through a column of Sephadex G-25 to separate unbound ^{59}Fe . The eluate was concentrated by ultrafiltration to approximately its original volume and glucose was added to a concentration of 1 mg ml^{-1} . This doubly labelled protein solution was then incubated with fresh cells and the ^{59}Fe and ^{55}Fe uptakes were measured. If site A were a better iron donor than site B, ^{59}Fe would be removed preferentially from site A in the first incubation and ^{55}Fe would preferentially occupy site A in the doubly labelled material. Therefore, a greater fraction of ^{59}Fe than of ^{55}Fe should be consumed in the second incubation. Alterna-

Fig. 2 Comparison of iron-donating abilities of monoferric and diferric transferrin. Blood from a patient with sickle cell anaemia (11% reticulocytes) was used for the upper experiment, in which the incubation mixture contained 0.13 mg transferrin per ml and had a haematocrit of 38%. Qualitatively similar results were obtained with blood from patients with iron deficiency anaemia (9% reticulocytes) and pernicious anaemia (12% reticulocytes). All incubation solutions contained bovine serum albumin (2 mg ml^{-1}) before adding cells. The experiments with rabbit cells have been described previously⁴, and are shown here for comparison, *a*, Human cells plus human protein; *b*, rabbit cells plus rabbit protein; *c*, rabbit cells plus human protein. Transferrin: ●, $^{59}\text{Fe}_1$; ■, $^{59}\text{Fe}_2$; ○, $^{59}\text{Fe}_1$ $^{55}\text{Fe}_1$.

tively, if the sites function equivalently, the same fraction of each isotope would be consumed in the second incubation. To compare the availability of iron in monoferric and diferric transferrin, monoferric ^{59}Fe -transferrin obtained by isoelectric focusing was brought to saturation with either ^{59}Fe or ^{55}Fe and uptake of ^{59}Fe from the monoferric and both diferric species was compared.

Results of the double incubation experiments are shown in Fig. 1. In both homologous systems (*a-d*) the ratio of the fractions of each isotope consumed is within experimental error of unity throughout each experiment, clearly indicating that one site of transferrin is not a better donor than the other. With rabbit reticulocytes and human transferrin (*e* and *f*) there is a preferential uptake of ^{59}Fe in the second incubation, as expected if one site is a better donor. Furthermore, the ratio of uptakes approaches unity with increasing total iron consumption since all of each isotope is potentially consumable. (Curves E and F are not expected to be identical because the fraction of iron consumed in the first incubation was not the same in each case.)

In Fig. 2 the availabilities of iron from monoferric and diferric transferrin are compared. Iron from monoferric human transferrin was slightly but consistently more available to human reticulocytes than iron from diferric transferrin in three different experiments, only one of which is shown. It should be noted, however, that since diferric transferrin carries twice as much iron as monoferric transferrin, it provides more total iron per unit time than monoferric transferrin. In the case of rabbit cells and rabbit protein, each iron atom of the monoferric and diferric species seemed to be equally available to reticulocytes. In the heterologous system of human protein and rabbit cells, monoferric transferrin was a somewhat poorer source of iron than diferric transferrin.

During our experiments we abandoned the use of albumin in the incubation medium when we became aware of its iron content. When analysed by atomic absorption spectroscopy, a solution of crystalline bovine serum albumin (10 mg ml^{-1} , Schwarz-Mann) contained $0.2\text{--}0.35 \mu\text{g Fe per ml}$. This would have been enough to affect the results of experiments comparing monoferric and diferric transferrin, were the iron available to the transferrin. Therefore, we studied the kinetics of iron uptake from monoferric human transferrin by rabbit reticulocytes in the presence or absence of albumin, or in the presence of albumin from which more than 90% of the iron had been removed by passage through a column of Chelex 100 (BioRad) equilibrated with 0.1 M sodium acetate, $\text{pH } 5.5$. No consistent effect of albumin on the rate of iron uptake was observed, so we cannot rule out the possibility that iron may have been transferred from albumin to transferrin in our conditions. Nevertheless, we think this unlikely in the absence of an iron-complexing agent to mediate transfer⁵.

Our results in Fig. 1 are inconsistent with the hypothesis of Fletcher and Huehns³. Experiments in support of this hypothesis are those of Awai *et al.*^{6,7} who studied iron uptake by rat tissue *in vivo*. The discrepancy between these results and ours may simply reflect the difference in species. We cannot however, account for the results of Awai *et al.* by a simple mathematical model. For example, consider the following experiment of theirs. Blood rich in reticulocytes was incubated with serum, in which the transferrin had been 90% saturated with ^{59}Fe , until only 35% of the iron remained. Assuming the greatest possible site preference, the remaining transferrin contained no ^{59}Fe at site A while site B still bound 70% of the ^{59}Fe originally present there. This was mixed with serum brought to 35% saturation with ^{55}Fe , so that sites A and B should each be 35% occupied by ^{55}Fe . In the resulting preparation, only ^{59}Fe should be present at site A, while a 2:1 ratio of ^{59}Fe to ^{55}Fe should be at site B. Even if a tissue has an absolute preference for site B, therefore, it should only consume a 2:1 ratio of ^{59}Fe : ^{55}Fe . Yet it was reported that this preparation delivered a 50:1 ratio of ^{59}Fe : ^{55}Fe to rat liver parenchymal cells (Table 1, in ref. 6).

It may be significant that in most ferrokinetic studies in man, 95–98% of the plasma radioiron clearance can be accounted for by a single rate constant^{8,9}. If the tracer is bound randomly to the sites of transferrin, this would indicate that the sites are at least kinetically, and very likely functionally, equivalent in their iron-donating properties.

Wavelength dependence of the bandwidths of visual pigment spectra

DARTNALL¹ proposed that the normalised absorption spectrum of any vitamin A₁-based visual pigment, when plotted on a frequency scale, could be fit to a standard shape, independent of its spectral absorbance maximum (λ_m). The existence of a standard shape implies that all pigments have the same band width. Dartnall devised an extremely useful nomogram so that given the λ_m of a pigment one could determine the entire shape of its main absorption band. A similar, slightly broader nomogram has been found for vitamin A₂-based pigments^{2,3}.

The validity of the idea that there are standard, λ_m -independent band shapes for all visual pigments, however, has been questioned^{4,5}. A clear trend has developed: spectra of blue-absorbing pigments tend to be broader than the nomogram, whereas red-absorbing pigments display spectra narrower than the appropriate nomograms. For example, the spectrum of the 432-nm frog cone pigment seems to be broader than the A₁ nomogram⁶. The action spectra of the 350-nm ultraviolet pigment and the 440-nm violet pigment in the moth *Deilephila elpenor* are clearly wider than the nomogram⁷; that of the 350-nm pigment is in turn considerably broader than that of the 440-nm pigment. Among the narrow, long wavelength spectra are those of the 620-nm tadpole pigment⁸, the 560-nm chicken cone pigment⁹, and the 625-nm goldfish cone pigment⁹. Smith and Pokorny⁵ have found that the nomogram does not describe the spectra of the long wavelength human cone pigments. In view of these findings, we investigated the theoretical guidelines governing visual pigment band shapes.

Several studies^{10,11} have described the spectral properties of the visual pigments in terms of those of two main classes of polyene molecules, cyanines and carotenoids. Cyanines, whose

Fig. 1 11-*cis* retinal (protonated) Schiff base. X, Fraction of protonation $0 \leq X \leq 1$, as explained in the text. Values of the dihedral angles ϕ are from Gilardi *et al.*²³

π electrons are essentially completely delocalised, have approximately equal bond lengths and narrow bandwidths (about $1,000 \text{ cm}^{-1}$). In carotenoids, the π electrons are not completely delocalised; there is considerable single bond–double bond alternation and bandwidths are broad (about $6,000 \text{ cm}^{-1}$)¹². As a result of their bond alternation, carotenoids absorb at considerably shorter wavelengths than cyanines of comparable length. The amount of bond alternation also affects the width of the absorption bands¹³. If a given electronic transition causes a large displacement of the equilibrium nuclear configuration along a particular normal coordinate, a vibrational progression due to that normal mode will appear in the spectrum: the larger the displacement, the greater the extent of vibrational broadening. In polyenes, the first excited state is one of little bond alternation¹². Thus excitation of carotenoids involves a large displacement of the equilibrium nuclear configuration and a correspondingly broadened absorption band. In the cyanines, bond alternation is already indistinct in the ground state and so excitation results in only small displacements in the equilibrium nuclear configuration and little vibrational broadening.

In visual pigments, retinal is bound by way of a Schiff base linkage to the protein. The Schiff base, at least in vertebrates, seems to be protonated¹⁴ (for a review of the evidence, see ref. 4). There is a large red shift from the spectrum of free retinal to that of rhodopsin and other visual pigments. Calculations¹⁵ using the Pariser–Parr–Pople¹⁶ (PPP) technique show that this spectral shift can be associated with the formation of the protonated $\text{C}=\text{N}^+$ bond. The resulting chromophore has an increased degree of π electron delocalisation and a corresponding decrease in bond alternation. The process involves, in effect, conversion of the chromophore from a carotenoid (high degree of bond alternation, short λ_m) to a cyanine-like (little bond alternation, long λ_m) molecule. Differences in absorption maxima between pigments are attributed to secondary interactions with the protein^{15,17}. The expectation, based on this analogy with polyenes, is that a decrease in bandwidth should accompany any increase in λ_m (ref. 4). It would be of interest to determine whether these qualitative considerations are borne out by detailed theoretical calculations.

Table 1 Calculated and experimental wavelengths, calculated bandwidth parameters, and experimental bandwidths for several model compounds

Molecule	$(\text{CH}_3)_2\text{N}-(\text{CH}=\text{CH})_4-\text{CH}=\text{N}^+(\text{CH}_3)_2$	$\text{O}^--(\text{CH}=\text{CH})_4-\text{CH}=\text{O}$	11- <i>cis</i> retinal (at the crystal conformation of Fig. 1)	11- <i>cis</i> retinal Schiff base (at the crystal conformation of Fig. 1)

0.6	498	0.0746
0.8	600	0.0631
1.0	670	0.0485

McCoy and Ross¹⁸ have found a direct correlation between a theoretically-derived parameter R and the shapes of electronic bands in aromatic systems. The parameter R relates the displacement of the equilibrium value of the bond lengths to the intensity distribution within the vibrational envelope of a transition. With Δr_j equal to the excitational change in the j th bond length, they consider the quantity

$$R = \left(\sum \Delta r_j^2 \right)^{1/2} \quad (1)$$

Here Δr_j can be calculated from the ground and excited state bond orders using the standard¹⁹ relationship between bond length r_j and bond order P_j ,

$$r_j = r_j^0 - \xi_j P_j \quad (2)$$

where r_j^0 is the ideal single bond length and ξ_j is the empirically determined slope.

Parameters for the calculations carried out here were obtained by fitting theoretical transition energies to experimental absorption maxima for a number of polyenes related to the visual chromophore. Table 1 compares calculated and experimental wavelengths for some of these model molecules. The fit of the absorption maxima is quite good. Moreover, we note that the trend in the calculated values of R parallels the experimental trend in bandwidths; R is large for carotenoids and small for cyanines.

Calculations involving the visual pigment chromophore were carried out on the π electron system consisting of atoms 5–16 in Fig. 1. To investigate the bandwidth parameter over a large range in λ_m , we varied the fraction of protonation on the nitrogen, x , from zero to one (Fig. 1). Suzuki *et al.*¹⁵ have shown that the amount of charge on the terminal nitrogen can control π -electron density in the bonds and thus the amount of bond alternation. Varying the amount of protonation mimics the more complicated chromophore-protein interactions which cause the observed variations in λ_m . Results for the protonated Schiff base (Table 2) show that the experimentally observed trends are reproduced by our calculations: R decreases as λ_m increases. Moreover, the numerical values of R in the range of visual pigment absorption maxima are intermediate between those of cyanines and carotenoids but closer to the latter. This is consistent with the observation that the width of the nomogram is 4,300 cm^{-1} .

In conclusion, we have shown that the (protonated) Schiff base model of visual pigments predicts bandwidths which are wavelength dependent. Moreover, the observed trend in pigment bandwidths can be understood in terms of the qualitative considerations presented here. Thus, it is not surprising that it is impossible to fit the spectra of all pigments to a standard band shape. Rather, any nomogram should be applicable only to a limited range of absorption maxima; in the case of the Dartnall nomogram, this range is from about 470–530 nm.

X-ray diffraction study of molecular structure and conformation of mezerein

THE crystal structure of one of the toxic components of the plant *Daphne mezereum*, mezerein, has been solved, unequivocally showing the molecular conformation in the solid state. Extracts from this plant have long been known to contain curative components, and have been used extensively in folk medicine in several countries¹. Mezerein has attracted attention for its anti-leukaemic activity against P-388 and P-1210 leukaemias in mice².

Many esters of phorbol (Fig. 1), which is closely related chemically to mezerein (Fig. 2), have also shown strong biological effects. Although these esters are reported to be extremely carcinogenic³, 12-hydroxy-daphnetoxin (Fig. 2) has no such activity. Furthermore, a range of esters of 12-hydro-daphnetoxin has significant antitumour activity⁴.

Because mezerein is the 5-phenyl-2,4-pentadionate ester of daphnetoxin, it would be interesting to know whether the attachment of this side chain changes the conformation of daphnetoxin or whether the biological activity is due solely to the added side chain. Also a knowledge of the architecture of this and related compounds will facilitate a systematic search for the biological systems affected by and the mode of action of chemical induction and inhibition of cancer.

Using a crystal of mezerein three-dimensional X-ray diffraction data were collected and reduced using conventional methods. The crystal belonged to the orthorhombic space group $P2_12_12_1$ with unit cell dimensions $a=13.45 \text{ \AA}$,

Fig. 1 Phorbol (the crystal structure of which has been solved by Brandl *et al.*⁷).

Fig. 2 12-Hydroxy-daphnetoxin (R = H), or mezerein (R = COCH-CHCH-CHC₆H₅).

$b=21.60 \text{ \AA}$ and $c=11.56 \text{ \AA}$, and contained one molecule per asymmetric unit. The structure was solved using direct methods and is at present refined to an R value of 0.131, using a full matrix least squares technique and isotropic temperature factors (details will be given elsewhere).

The molecular structure of the compound looks extremely compact, except for the 5-phenyl-2,4-pentadionate side chain. The fused-ring systems consisting of three, five, six and seven-membered rings form a cluster of roughly spherical shape (Fig. 3). The conformation of the central part of the molecule compares with that of 12-hydroxy-daphnetoxin^{5,6}. The cyclohexane ring is in a slightly twisted boat conformation. The structure of the cycloheptane ring can be regarded as that of a basal plane consisting of five carbon atoms of which the carbon-carbon bond involved in the epoxide ring is a member. At an angle of 110° to this plane the plane defined by the two bonds shared with the five-membered ring and the six-membered ring is attached.

Fig. 3 A computer-generated drawing of the molecular structure of mezerein based on crystallographic data.

There seems to be conformational identity between the molecular structures of mezerein and that of 12-hydroxy-daphnetoxin tribromoacetate in the crystalline state⁶. In addition, due to the rigidity of the molecular framework caused by the attachment of various ring systems to the cycloheptane ring, it is most unlikely that the solution conformations are significantly changed.

We can thus conclude that the observed antitumour activity is somehow connected to the added ester at position 12. As Kupchan *et al.* pointed out⁴, the affixed ester may be involved in processes associated with cell wall penetration. In this connection it might be pointed out that the diterpene is in its fully extended form. An important question remains: at which step in the cellular metabolism is the toxic effect of mezerein and its analogue exerted, and which of the functional groups are active?

The crystal of mezerein used in this study was supplied by A. Groth and R. Söderquist, FOA, Stockholm, Sweden.

Use of macromolecules in microparticles

POLYMERS of acrylamide, dextran, Agarose, and their derivatives have been used widely as matrices for covalent immobilisation of enzymes, for example, for biospecific affinity chromatography¹. Macromolecules can also be trapped in acrylic polymers, when added to the monomer solution before polymerisation²⁻⁴. Spherical polymeric particles are produced by homogenising the monomer solution with a suitable detergent in an organic solvent or mixture, in such a way as to produce a water-oil emulsion before polymerisation. The size of the polymeric particles will be directly proportional to the size of the droplets of the monomeric solution in the organic phase, giving a narrow size-distribution of the particles. The mean diameter can be varied greatly by changing the homogenising conditions. Hitherto, the aim has been to prepare particles with a mean diameter of 100-250 μm , to ensure a high flow rate when they are packed in columns. We have now found, however, that macromolecules trapped in the particles, retain their biological properties, and that therefore, microparticles

Fig. 1 Scanning electron micrographs. *a*, Polyacrylamide particle obtained by bead polymerisation; *b*, detail of microparticle. Bars, 1 μm .

with mean diameter $<10\ \mu\text{m}$ can conveniently be used for several other purposes in widely different fields.

In the polymerisation procedure, we used acrylamide (1.5 g) and N,N' -methylene-bisacrylamide (0.5 g) in 25 ml of phosphate buffer, 0.005 M, pH 7.5, in which the protein (10–100 mg ml^{-1}) was dissolved. The catalyst system, consisting of ammonium peroxodisulphate (10 μg in 50 μl) and N,N,N',N' -tetramethyl-ethylenediamine (50 μl), was added to the monomer solution immediately before the homogenisation in toluene-chloroform (4 : 1, 300 ml). The detergent (Pluronic F68, Wyandotte Chemical Corp., Wyandotte, Michigan, 0.25 g) was dissolved in the organic phase. After the polymerisation, which was completed in about 10 min, the particles obtained were thoroughly washed with water and centrifuged. A more detailed description of the preparation procedure and the characteristics of the microparticles will be given elsewhere.

The amount of protein trapped, determined after acid hydrolysis, is directly proportional to its concentration in the monomer solution. Protein not trapped in the particles is found both in the water phase and the first washings. The polymeric network trapping the proteins is very porous, facilitating good penetration of the particles by reasonably large molecules, as is evident from Fig. 1. The equilibrium with the entrapped macromolecules is, therefore, reached very rapidly. Different macromolecule–ligand interactions, for example drug–protein or protein–protein interactions, can thus be easily studied using the microparticles. The material to be studied is suspended in an appropriate buffer, in which the particles with entrapped macromolecules will form a separate phase which can be isolated by centrifugation. During prolonged incubation in the buffer only insignificant numbers of macromolecules leak out of the particles. The particles can also serve as a matrix for different macromolecular reagents, for example in radioimmunoassays.

Fig. 2 Photomicrographs of fluorescein-labelled microparticles, containing concanavalin A, interacting with human erythrocytes, at pH 7.4 in 0.9% NaCl with 0.001 M CaCl_2 , 0.001 M MnCl_2 , 0.001 M MgCl_2 and 0.02% merthiolate. The photographs show the same cells in *a*, visible light; and *b*, blue light (about 490 nm).

The binding properties of the macromolecules trapped in acrylic polymers are unchanged. Thus, for instance, the binding of salicylic acid and warfarin to albumin is the same when immobilised in macroparticles as in equilibrium dialysis, with albumin in free form in the buffer. This enables binding studies to be performed in a suspension of particles, which can be isolated by centrifugation after brief incubation, obviating time consuming and laborious methods, such as equilibrium dialysis with semipermeable membranes. The use of microparticles containing albumin should greatly simplify the analysis of the drug-binding capacity of individual patient sera, enabling an individualised dosage regimen, using potent protein-bound drugs, to be achieved. Methods are being developed for this purpose, based on the competitive protein-binding principle.

A remarkable feature of the entrapped macromolecules is their availability on the surface of the microparticles, enabling them to interact with biological cells. Figure 2 shows how microparticles containing 2% concanavalin A (con A) and labelled with fluorescein isothiocyanate, have formed complexes with human erythrocytes. Particles not containing any con A will not show any significant affinity for the erythrocytes. In preliminary experiments it has also been shown that microparticles containing protein A from *Staphylococcus aureus*, known to react with the Fc part of IgG molecules⁵, are completely retained (at pH 7.4, in 0.1 M NaCl) on a Sepharose column, to which normal human immunoglobulin is covalently bound. Apparently, the polyacrylamide network allows sections of the protein to stick out of the microparticles, and to react with cells or Sepharose particles, but is compact enough to keep other sections of the protein molecules fixed in the particles.

The discovery that the macromolecules are accessible to specific membrane structures on the cell surface, opens up wide perspectives for the separation and characterisation of cells with specific surface structures. The separation of cells has hitherto been based mainly on centrifugation in density gradients, and results in bands of cells of the same density.

In a cell population of the same density, however, different cells can have different surface properties. Advantage has been taken of this to separate cells on, amongst others, nylon nets, to which biospecific molecules are bound⁶, or on biospecific Sepharose columns⁷. The microparticles, in which specific macromolecules are trapped, can be used for the same purposes. After a group of cells has been separated in a density gradient, the microparticles can be used to change the density of cells bearing the receptor for which the macromolecules have affinity. Repeated gradient centrifugation will then separate these cells. This general principle can be used in several different applications.

The microparticles can easily be labelled, with different fluorescent reagents, for example, large amounts of which can be bound to inactive macromolecules trapped in the particles. Combined with specific cell-markers (antibodies, agglutinins), such microparticles can be used to detect specific cell membrane structures using fluorescence microscopy. Such an application can be used in different cell studies, as well as for diagnostic purposes, the importance of which cannot yet be foreseen.

matters arising

GFA protein in C-6 glioma *in vitro*

BISSELL *et al.* reported a 40-fold increase of glial fibrillary acidic (GFA) protein by radioimmunoassay in buffer extracts of C-6 glioma cells maintained in organ culture, compared with the same cells in monolayer and suspension culture¹. Quantitative data using buffer extracts should be interpreted with caution, since they may indicate differences in solubility rather than in total amounts. GFA protein is only partially soluble in water^{2,3}, and the factors regulating the ratio between water-soluble and insoluble fractions are still poorly understood. Solubility in buffer is greatly increased by *in situ* proteolysis⁴, and may be seen to vary considerably in different regions of the brain, even when a relatively insensitive assay such as double immunodiffusion is used.

BISSELL *ET AL.* REPLY—Bignami¹ raises the question whether our reported data on the quantitative increase of GFA protein in C-6 glioma cells *in vitro*² might not indicate differences in solubility rather than in total amounts. We welcome this opportunity to stress that the GFA protein estimations in our study were determined only on the phosphate buffer-soluble fraction. We have of course long been aware³ of the existence of water-soluble and insoluble GFA protein fractions, and we agree that the chemical relationship between the two and the

protein and of the stability and immunological identity of the purified and impure antigen, followed by a discussion on the soluble compared with insoluble GFA protein fractions, is to appear soon⁵. Contrary to Bignami's experience, our purified GFA protein standard (prepared from frozen human multiple sclerosis plaques) did not change in two-site IRMA immunoactivity for at least six months. In our report all samples were measured using the same standard.

Table 1 Solubility of GFA protein in different regions of the brain indicated by the immunodiffusion titre with GFA protein antiserum

	Water-soluble fraction	Urea-soluble fraction (first extract)
Cerebral cortex	1/4	1/4
Cerebral white matter	< 1*	1/32
Brain stem	1/8	1/16

Bovine brains were frozen at the slaughterhouse and GFA protein was extracted in 0.05 M sodium phosphate buffer, pH 8.0, with and without 6 M urea (w/v, 1:4).

* Precipitin lines were not observed against undiluted GFA protein antiserum unless the well was filled 2-3 times with the white matter extract.

As Table 1 shows, the white matter contains larger amounts than the cerebral cortex, which agrees with its relatively larger content of astroglia. However, the reverse is true for the water-soluble fraction, that is, only small amounts are extractable in buffer from the white matter compared with the cortex.

An additional point is that the radioimmunoassay for GFA protein⁵ is difficult to reproduce, since no information is given on the preparation of the standard. Our experience with micro-complement fixation indicates that GFA protein not only precipitates from the standard solution kept at 4 °C or frozen, but also that in these conditions the immunological activity per unit protein steadily decreases in the high-speed supernatant (100,000g for 1 h).

factors influencing their relative concentrations are still poorly understood. To assign, therefore, any special significance to either is premature. On the other hand, while we cannot exclude the hypothesis that variations in solubility could have played some role in determining minor deviations in the quantitative data obtained in our study, the overall reproducibility of the assays and the fact that they so unequivocally confirm previous observations on the same system using an immunofluorescence technique⁴ make it unlikely that solubility differences would account in any significant measure for the striking increases observed. The relevance of Bignami's table in relation to our report is questionable because the heterogeneity of astroglial cell populations that prevail in the different regions of the brain does not apply to the homogeneous cloned cell system used in our study.

A description of the properties of the two-site IRMA assay for the GFA

Tropomyosin and actin

BECAUSE of changes introduced before publication, Parry's letter¹ was not quite that to which my reply² was addressed. I wish to point out that his suggestion that tropomyosin would present pseudo-equivalent aspects to all seven actins is simply a restatement of my original hypothesis³. This hypothesis is strengthened by the observation of several charged groups in the sequence⁴ repeating at exactly 77 residues. The computed coordinates of these show that some could lie at the correct positions to interact with one strand of actin.

PHA and lymphocyte membrane fluidity

BARNETT *et al.*¹ reported that mitogenic lectins induce changes in the fluidity of lymphocyte membranes, which can be detected by means of the spin label electron spin resonance (ESR) technique. This finding, if substantiated, would be

of great importance in understanding the processes leading to mitosis. Considerable doubt has, however, been cast on the interpretation of Barnett's results, by the fact that the spin label used has since turned out to be a mixture of three compounds². Consequently, an independent study has been undertaken to examine the effects of the mitogen phytohaemagglutinin (PHA), using several different spin labels that probe different regions of the membrane.

The cells examined were human tonsil lymphocytes, separated (>90% purity) by teasing through a mesh and suspended in Hank's medium. ESR measurements were made using a Varian E-9, X-band spectrometer, equipped with a variable temperature accessory and a dual cavity operating in the H_{014} mode. Quantitation of the spectra was aided by the use of a Nicolet 1020A signal averager. Spin labels were purchased from the Syva Corporation, Palo Alto, California. These were the androstane label

and the stearic acid labels

where $m = 1$, $n = 14$; $m = 5$, $n = 10$ and $m = 12$, $n = 3$. All these labels are known to incorporate into the lipid regions of membranes. Two different methods were used to label the cells, namely deposition of the label on to the walls of a flask by evaporation of an alcoholic solution, and addition of $1 \mu\text{l}$ of a 10^{-1} M solution of label in ethanol to 1 ml of cell suspension. In both cases, cells were incubated with the label for 15 min at 37°C . They were then washed three times with medium, to remove free label and resuspended. A third method was also tried for label I ($m = 12$; $n = 3$), this being dissolved in an aqueous solution of sodium carbonate before addition to the cell suspension; however the method of introduction of label seemed to have no influence on the results obtained. Introduction of a spin label into the cells also had no detectable effect on their integrity. The PHA used

was Wellcome purified reagent. The optimum mitogenic dose for this material was found to be $1 \mu\text{g ml}^{-1}$ and this is the concentration used, except in one experiment where a higher dose ($10 \mu\text{g ml}^{-1}$) was used.

The androstane label and the stearic acid label I ($m=1$; $n=14$) both gave weakly immobilised, three-line spectra when added to the tonsil lymphocytes. The ratio of the heights of the three lines, which gives a measure of the mobility of the label³, was found to be unaffected by incubation with PHA for times up to 90 min. The label I ($m=5$; $n=10$) gave a complex spectrum showing both weakly and strongly immobilised components, possibly a result of some localisation of the polar nitroxide group in a hydrophilic region. Although difficult to analyse, this showed no detectable change with PHA. The label I ($m=12$; $n=3$) gave a strongly immobilised 'powder' spectrum when incorporated in the cells. From the separation of the extrema, an order parameter, S , was calculated⁴. This was determined with an accuracy of $\pm 1\%$ by means of the Nicolet 1020A. No change in the value of S could be detected, up to 90 min after the addition of PHA at 37°C . Use of a higher concentration of PHA also showed no effect on the value of S . When spectra were recorded at $21 \pm 1^\circ\text{C}$, the values of S were 0.678 ± 0.004 in the absence of PHA and 0.674 ± 0.007 in the presence of PHA. When measurements were made at 35°C , the fluidity of the membrane was increased and the value of S correspondingly reduced to 0.57 ± 0.01 .

In one experiment, cells were suspended in medium containing serum, in order to promote growth. As previously reported⁵, however, it was found that after introduction of spin label the observed spectrum was due primarily to label complexed with serum albumin.

Investigations into the fluidity of erythrocyte membranes in myotonic muscular dystrophy⁶ suggest that the spectral amplitude ratio A/B is more sensitive to change than the order parameter, S .

Consequently the present spectra were also analysed in terms of this parameter, but in no case could any change as a result of PHA be detected.

The present results indicate that PHA has no demonstrable effect on the fluidity of human tonsil lymphocyte membranes and it is unlikely that other human lymphocytes will behave differently. An alternative interpretation of the findings of Barnett *et al.*¹ must therefore be found. Since individual labels, in the mixture they used, would give differing values for the order parameter, the changes following mitogenic stimulation are consistent with a change in the relative proportions of the three labels present in the membranes. The cause of such a change could be as important as the apparent change in fluidity to which it was ascribed and this is now being investigated.

I thank Drs M. Moore and M. R. Potter of the Immunology Section for help and advice. The work was supported by the MRC.

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

FIDDLER CRABS OF THE WORLD

(Ocypodidae: Genus *Uca*)
JOCELYN CRANE

The book is divided into two sections. The first is a thorough systematic revision, including the only taxonomic revision of the entire genus since 1880. The second section, "Towards an Evolutionary Synthesis," considers the genus as a whole, from the viewpoints of biogeography, ecology, morphology, and behavior. "In one monumental work Jocelyn Crane has brought together everything that is known

about fiddler crabs (much of it from her own studies), and she has made a synthesis that will be important to systematists, ecologists, behaviorists, and evolutionists."—*John T. Bonner*

INTRODUCTION TO GEOLOGY: Volume 2 EARTH HISTORY

**H.H. Read
& Janet Watson**

Part 1 EARLY STAGES OF
EARTH HISTORY
Part 2 LATER STAGES OF
EARTH HISTORY

This scholarly work by two acknowledged experts consists of two parts which together provide a comprehensive outline of earth history covering the whole of the geological time span as well as every continent. Part 1 carries the record to late Precambrian times, Part 2 covers the last thousand million years.

The authors have integrated the records of events that took place at or near the earth's surface with those of tectonic, metamorphic and magmatic events occurring at depth in the crust. The development of large geological units such as mobile belts and basins of deposition are emphasised. Local details are presented where appropriate in relation to the evolution of these units. Economic deposits are discussed in the same context.

The treatment of earth history is based on the concept of a long-term rhythm in the mobility of the earth's crust. The principal divisions of the two Parts deal with successive repetitions of this crustal rhythm, while individual chapters are arranged on a regional basis.

This is the second volume of *Introduction to Geology*. Volume 1, *Principles*, was first published in 1962, with a revised second edition in 1968.

Volume 2
Part 1 hardcover £5 95, paperback £2 95
Part 2 hardcover £6.95, paperback £3 95

reviews

WAVES of various kinds are present in the atmosphere and the study of their generation, propagation and interaction is of great importance to meteorologists and aeronomers. Compressibility and buoyancy effects due to the action of gravity on vertical density gradients provide the main restoring forces for waves of comparatively short wavelength, with Coriolis effects increasing in importance with horizontal wavelength and becoming dominant for planetary-scale waves. Hydromagnetic effects due to the presence of the Earth's magnetic field complicate wave propagation in the electrically-conducting ionosphere.

Numerous observations of atmospheric waves are now available, thanks to the introduction of a variety of new techniques, including radar and acoustic echo sounders. The first of the three books listed above is an excellent systematic account of meso-scale and small-scale waves dominated by compressibility and buoyancy. It starts with an historical survey and particularly lucid discussions of the basic equations of fluid dynamics and of various theoretical concepts required in the study of wave propagation. Some boundary value problems arising in the analysis of wave-propagation in non-uniform media are then considered. Chapter 6 is largely concerned with various stability problems and the theory of the generation of atmospheric gravity waves, and chapter 7 with the theory of dissipative effects. Observations of gravity waves and infra-sound and

Air waves

R. Hide

Waves in the Atmosphere: Atmospheric Intra-Sound and Gravity Waves—Their Generation and Propagation.

By Earl E. Gossard and William H. Hooke. Pp. xv+456. (Developments in Atmospheric Science, volume 2.) (Elsevier Scientific: Amsterdam, Oxford and New York, 1975.) \$64.95; Dfl 156.00. *Atmospheric Waves.* By Tom Beer. Pp. xvi+300. (Adam Hilger: London, October, 1974.) £16.00. *The Upper Atmosphere in Motion: A Selection of Papers, with Annotation.* (Geophysical Monograph No. 18.) By C. O. Hines and Colleagues. Pp. xii+1,072. (American Geophysical Union: Washington, DC, 1974.) n.p.

considerations of energy sources are presented in chapters 8–10, which include some particularly valuable case studies. Waves in the upper atmosphere are the subject of the eleventh and final chapter. This carefully prepared and well illustrated book can be highly recommended to graduate students and research workers in atmospheric physics.

The book written by Beer cannot, unfortunately, be highly recommended, owing to its many errors and muddled presentation of key ideas and results. This is a great pity because the publishers have gone to a great deal of trouble to produce

a handsome and well-illustrated volume, and there is certainly a need for a good treatise on the material covered, which includes treatments of waves on all scales.

Hines' book is altogether different from the other two, and it is by no means clear for whom the book is intended, apart from those specialists who may wish to possess in one volume a collection of excellent papers by one of the pioneers of research on waves in the upper atmosphere and his collaborators, together with a very personal and somewhat idiosyncratic commentary on each paper by the author. In the introduction to the book the author states that "... although I have by no means ignored my fellow professionals in making my commentary ... my thoughts were primarily with the student reader and my design was to provide him or her with a full view of the sort of workings that go on behind the development of a field. Scientific convention normally bars such exposure from orderly textbooks, but this unconventional format provided me with an unusual opportunity—one that normally arises in direct contact with students—and I have not hesitated to exploit it, hopefully for the benefit of students elsewhere". Some future historian of aeronomy will doubtless acknowledge the enterprise of the American Geophysical Union in making this material available, but few science students will have the time to pursue these fascinating byways. □

THERE are already available several comprehensive accounts of nuclear structure, but this volume is assured of a worthy place by reason of its clarity of exposition, attention to detail and coverage of the most recent advances.

The opening chapter is naturally devoted to the nucleon–nucleon force, and contains a very thorough account of its meson-theoretical basis. It is followed by a summary of our knowledge of the shapes of nuclei and of their electric and magnetic moments. Subsequent chapters are devoted to the various models that enable us to correlate and understand so many features of nuclear structure, starting with the statistical model and the associated

topics of the semi-empirical mass formula and infinite nuclear matter. There is a detailed account of the

Nuclear structure

P. E. Hodgson

Nuclear Structure. By William F. Hornyak. Pp. xii+605. (Academic: New York and London, July 1975.) \$49.50; £23.75.

single-particle model, showing how a simple one-body potential is able to account for so many features.

Substantial chapters follow on the individual particle or shell model and on the collective models. That on the shell model contains an

account of the coupling schemes and the general symmetry classifications, together with intermediate coupling and the cluster model. The account of collective models covers the classical liquid-drop model, the vibrational states of spherical nuclei and the collective states of deformed nuclei. Two concluding chapters are devoted to the electromagnetic interactions of nuclei and β decay, and there are appendices on angular momentum coupling and on the Wigner–Eckart theorem.

The level of presentation is intended to be that appropriate to a second-year graduate student, but the book will also be found valuable by senior undergraduates and established physicists. □

Proton-Transfer Reactions

Edited by E. F. CALDIN and V. GOLD, F.R.S.
1975: 456 pages: illustrated: 412 12700 8:
hardback: £18.00

Many of the fundamental concepts of chemistry – from the tunnel effect in chemical kinetics to catalysis by enzymes – owe their recognition or formulation to the study of proton-transfer reactions. The subject has been developed in extensive researches by many workers, and most notably by Professor R. P. Bell, whose book *The Proton in Chemistry* has become a modern classic of science. The present volume, dedicated to Professor Bell, aims to complement his book by providing a coordinated set of studies in depth on some of the central problems and growing-points of proton-transfer reactions, written by a group of leading workers in the field

Second Edition

Biochemistry of Antimicrobial Action

T. J. FRANKLIN and G. A. SNOW
Hardback: Second edition 1975: 240 pages:
7 tone and 78 line illustrations: 412 12900 0:
£7.00

Science Paperback: 412 12910 8: £3.95

This book provides a systematic guide to the field of antimicrobial biochemistry. The mechanisms by which antimicrobial agents have their effect are illustrated by a large number of examples, leading to a discussion of the development of drug resistance in micro-organisms. Extensive revisions have been made in this second edition and these include substantial changes in virtually every chapter. A new chapter has been added on the penetration of antimicrobial agents into cells.

Second Edition

Lipid Biochemistry

M. I. GURR and A. T. JAMES
Hardback: Second edition November 1975:
256 pages: illustrated: 412 13780 1: £6.50
Science Paperback: 412 13790 9: £3.95

This new edition has been thoroughly updated and the authors have added new material where appropriate – as, for example, the latest knowledge on the pathway for the biosynthesis of ether bonds. A new chapter *Lipids in food*, has also been added for the new edition. This chapter not only covers the biochemistry and physiology of dietary fats but also their role in the texture, flavour and aroma of foods. It also includes a discussion of diseases (heart disease, obesity, diabetes) in which dietary fats are thought to play a role.

Dynamic molecules

Molecular Reaction Dynamics. By R. D. Levine and R. B. Bernstein. Pp. vi+150. (Clarendon: Oxford; Oxford University Press: New York, November 1975.) £5.00.

THE last fifteen years have seen rapid progress in one of the most fundamental areas of chemical research—the awakening of our understanding of how reactions occur at the microscopic level. Indeed much of this work is so recent that an adequate grasp of the field can only be acquired after extensive perusal of the original literature and the relatively limited number of research reviews. It is for this reason that the appearance of Levine and Bernstein's *Molecular Reaction Dynamics* is particularly welcome at this time.

The book is directed at 'newcomers' to the field and contains material which has been presented orally to advanced undergraduates and, presumably, graduate students. The contents are organised into six chapters which make up a total of some 30 sections, most of which are subdivided further. The avowed aim is to provide a general feeling for the whole subject area rather than supply extensive detailed knowledge, and as such the volume is, as it sets out to be, much more of a 'course book' than a reference work. Chapter 1 serves to whet the appetite for the study of molecular dynamics, after which the logic is to initiate a detailed consideration of molecular collisions (chapter 2) as a prelude to an account of how scattering phenomena can be related to collision dynamics (chapter 3). This leads to a consideration of the trajectories across potential energy surfaces, the theoretical calculation of reaction rates, the relationship between micro- and macroscopic observations, the partitioning between the different forms of energy in the products (chapter 4) and a survey of the different forms of molecular energy transfer (chapter 5). The climax of this development is then experienced in chapter 6 in which the previous extensive preparation is applied to the experimental study and discussion of a series of chemical systems exhibiting respectively different types of interaction between the reacting species. The various sections of the book are adequately cross-referenced forwards and backwards.

The method of presentation is such that maximum value can only be derived from the text by reading it cover-to-cover a number of times, and a newcomer would only acquire a real understanding of some of the

mathematical material after a prolonged study of the relevant published literature. An annoying and distracting feature, which seems to be characteristic generally of 'beam' publications, is the extensive use of footnotes, often containing asides or amplifications of the discussion, which could readily be either omitted or incorporated into the main text. Apart these objections, however, the book undoubtedly satisfies the need for a readable and comprehensive guide to this important area of study at an attractive price. J. F. J. Todd

Numbers

Transcendental Number Theory. By Alan Baker. Pp. x+147. (Cambridge University Press: London, April 1975.) £4.90; \$13.95.

A NUMBER is said to be algebraic if it is a root of a non-zero polynomial in one variable, the coefficients of which are integers, and to be transcendental otherwise. It is well-known that (in a measure theoretic sense) almost all numbers are transcendental, but to demonstrate that a specific number is transcendental is never trivial. The methods for solving this problem constitute transcendental number theory.

Professor Baker's tract is an account of the advances in this subject during the last decade. A short description of the origins of the theory is followed by an amalgam of the author's award-winning papers (Fields Medal) on linear forms in logarithms with some very interesting applications both in transcendence theory and in such other areas as Diophantine equations and Gauss's conjecture on discriminants of class number one. Further topics include Schmidt's theorem on simultaneous approximation of several algebraic numbers by rationals, Mahler's classification of transcendental numbers and Shidlovsky's theorem on algebraic independence.

The proofs of the major theorems are presented in a very economic style and can be fully understood only by students with a plentiful supply of pencil, paper and time. For such serious students the book will form an admirable introduction to this difficult field of research, being in addition a concise source book for the major additional developments and outstanding problems. Those wishing to obtain an appreciation of the scope of this field will also gain much from the more descriptive parts of the work. All readers of this timely and welcome tract will benefit from the appraisal of a pre-eminent contributor to the field. D. A. Burgess

Urban environmental management

Urban Environmental Management. By Brian J. L. Berry and Frank E. Horton. Pp. xv+425. (Prentice-Hall: Englewood Cliffs, 1974.) \$14.95.

BRIAN BERRY and Frank Horton have discovered a new way to produce large text books—the 'text with integrated readings'. They now follow their *Geographical Perspectives on Urban Systems* with a new text on urban environmental management. They produce a cross between a reader and a traditional textbook by using contributors' papers, as in the former, but integrating them with judicious introductory and linking texts of their own. This makes it possible to be the first in the field with a new book. But does it work?

Although many of the contributing authors are first class, the present book is very uneven. Many of the articles used first appeared in that excellent journal *Science* and serve as thorough introductions. Most of the rest are either university discussion papers or government papers. These often contain masses of information, ranging in content, for example, from 'Generation of Solid Wastes from Five Major Sources in 1967' (covering the whole of the USA with no reference cited) to 'Licensed Swine Feeders in Northeastern Illinois' (reference given this time). Not surprisingly, it is very difficult for the reader to get all this into perspective. Absolute figures for 1967 do not say whether the problem is getting worse and if so at what rate.

Successive groups of chapter are concerned with environmental beliefs, environmental impacts of urbanisation, air, water, solid wastes, noise, the relationship between environmental pollution and health, and government programmes. Quite an agenda. The student is introduced to most of the basic elements of the various sectors, but he will sometimes, one suspects, have to be wary of the arguments put. For example, it is argued that particulate concentration increases with city size on the basis of a regression of the geometric mean of the pollutant against the log of the population, January temperature and the number of iron and steel production workers. Presumably, these were the best of the variables tried; the R^2 was 0.26. There are other examples of feeble analysis.

So the student gets his text a couple of years before he can have a 'proper' one, and lots of research workers who need a quick introduction to an important new field, can get it. But the price is fairly high. The quality of what is on offer varies tremendously, and the authors/editors have not always helped. They do indicate where a new reading starts, roughly, but not where it finishes, so it is not always

clear who is responsible for a piece of text—a bad principle to introduce. Many, if not most, of the entries in a long list of references are not actually cited in the text, and so the reader is not provided with an adequate guide to the literature. All in all, it may have been better for Berry and Horton to have been more patient before using their obvious skills in producing a conventional text.

A. G. Wilson

A fishspear from the Lipari Islands, off the coast of Sicily, probably used for funny fish. Taken from *Beachcombing for Beginners* by Norman Hicklin Pp. v+128. (David and Charles: London, 1975.) £3.50.

Insect muscle

Insect Muscle. Edited by P. N. R. Usherwood. Pp. xi+621. (Academic: London and New York, May 1975.) £14.50; \$38.25.

PHYSIOLOGISTS disagree as to whether diversity is a subject worthy of study in its own right but none would dissent from the view that a correct choice of experimental material is important for the investigation of basic biological phenomena. It has been amply demonstrated that insect muscle can provide many such opportunities. By contrast, it cannot be claimed that the study of insect muscles has yet made any important contributions to applied entomology. Workers who are interested in practical control measures can omit this book from their reading for the time being. It might become important introductory material for them in 10 years time when other aspects of insect physiology are better understood. Otherwise, however, this is a useful and timely book which should be read by all

general physiologists interested in the problem of muscular contractility.

Elder starts with a good review of all the significant, fine structural aspects of insects muscles. Finlayson deals with the difficult subject of development and degeneration, but in a book of this sort the articles should be more than a catalogue of original sources of information and should bring out points of significance. In fact, many of the articles meet this criterion.

On neuromuscular physiology, Osborne gives a good discussion of ultrastructural aspects and Usherwood and Cull-Candy provide a review of the difficult field of the identity of transmitters; their summary tables on the action of various chemical substances will be much used for reference. Piek, dealing with ionic and electrical properties, suggests that a highly active Na-K exchange pump operates in the extensive transverse tubular membrane, that this membrane is permeable to chloride and that this leads to a concentration of NaCl in the transverse tubular space which is high enough to produce a significant liquid junctional potential at its opening.

Aidley gives a short review of excitation-contraction coupling and mechanical properties, which is adequate in view of the fact that few significant differences have been discovered between insect and vertebrate muscles. Tregear presents a major review of the use made of a fibrillar muscle preparation for the elucidation of basic mechanisms of mechanochemical transduction; insect muscle had made important contributions to this general problem. Crabtree and Newsholme, on metabolism, return to an emphasis on diversity. Whereas the basic molecular mechanism for contraction seems to be the same for all muscles, differences in the type of fuel used for metabolic generation of ATP reflect the adaptation of the tissue to the needs of the whole animal, which are different for different insects. The article contains a lot of information and an interesting discussion of regulatory mechanisms and the nature and role of reversible mitochondrial shuttles. Hoyle, on neural control, is concerned with the programming of the output of motor neurones. Insect movement provides several well defined patterns of coordination, the analysis of which offers hope for a better understanding of the organisation of the central nervous system. This is an active and significant area of research. The last chapter, by Miller on visceral muscles, is a tasty *hors d'oeuvre* which, I hope, will stimulate the appetite of comparative physiologists for a field that cannot fail to integrate several aspects of insect biology.

The book is well produced and Professor Usherwood deserves our gratitude for undertaking the editorial tasks.

Belts of ignorance

The Geology of Continental Margins. Edited by Creighton A. Burke, Charles L. Drake. Pp. xiii+1009. (Springer: Berlin and New York, 1974.) DM85.30; \$34.80.

FOR 600 million years the level of the North American continent as a block seems to have deviated by less than 60 m from the levels of the surrounding oceans. Yet during that time the Atlantic and Indian oceans came into being, the shape of the Pacific must have changed considerably, and the entire ocean floor has been renewed possibly twice or thrice. There must, therefore, be some mechanism which maintains a balance between the capacity of the ocean basins and the quantity of water available to fill them. It is very difficult at the moment to see what this mechanism may be. That is but one of the problems to which this book contributes.

The book provides a first rate summary of what is known about the continental margins—belts of ignorance as they have been termed—which extend sinuously across the Earth's surface for 350,000 km. These remarkable regions, which were necessarily ignored by the early landbound geologists and which have to some extent been left on one side by the recent rapid advances in our knowledge of the deep oceans, remain of critical importance.

It has long been known that sediments produced by the wearing away of continents contribute to the continental shelves, but what has become clear only in recent years is the effective way that such deposits are retained near the continents and the small extent to which they contribute to the sediments of the deep oceans. We now know of some of the ways in which sedimentary material is clawed back to form, once more, parts of a modified continental crust.

This book provides both a synoptic view of the margins of the present day continents and a conspectus of more general matters, such as bathymetry, the transition from continent to ocean, recent sedimentation, and the deformation of continental margins, all of which are treated in a score of contributions. The latter parts of this 1,000-page book deal with problems of the small ocean basins, such as the Black Sea or the Mediterranean, and with questions concerning ancient continental margins, the subject of a dozen or so papers. There is no index, but an excellent concluding article by the editors puts matters in perspective in an effective fashion, and the lay-out, consisting as it does partly of articles grouped under general headings, and partly of articles dealing with geographical regions, makes reference not too difficult. Nonetheless, in my opinion an index would have been a most useful addition.

One of the main virtues of this book arises as a result of the factual information that it contains, arranged as it is in a readily accessible fashion. But perhaps of greater importance are the discussions of still wider problems, which come up time and again. Why are continental margins situated where they are? How is it that, despite the great changes in the shape and distribution of oceans, the water rarely overflows on to the continents by more than a few tens of metres? One gets a vivid impression of the way in which geophysical evidence as to the structures of recent continental margins, supplemented by drilling, is bringing our knowledge to a point from which direct comparisons can be made with the remnants of ancient continental margins whose structures have been gradually pieced together by two centuries of geological enquiry.

From an economic point of view one is left with an intriguing question: whether petroleum may be present within the continental rise, the deepest lying part of the continental margin. Existing technology could probably be developed to recover hydrocarbons, should they be present, from the sediments of the continental rise, though these are covered by as much as 2–3 km of water.

All in all this is a first class book which does justice to the immensity of its subject.

J. Sutton

Aggression

Determinants and Origins of Aggressive Behaviour. (New Babylon: Studies in the Social Sciences, vol. 22.) Edited by Jan de Wit and Willard W. Hartup. Pp. xiv+623. (Mouton: The Hague and Paris, 1974.) Dfl.84.

THE papers in this collection “were prepared for” or, alternatively, “grew out of” a NATO conference held in Monaco two years ago. The first and more modest estimate of their origins is that of the editors, whose thoughtful concluding paper testifies to the limits of growth that can be expected from such a conference. The 45 papers embrace a good range of current experimental approaches to the understanding of aggressive behaviour: the perspectives of ethology, physiological psychology, psychogenetics, social psychology, psychometry, pharmacology, psychopathology and anthropology are all represented to some degree.

In such a jamboree, coherence is almost inevitably missing. At least, the editors make little pretence of finding it: their own consideration of the effects of domestic punishment on children's aggression in other situations involves alarming discrepancy across just 11 pages; and at no point does their discussion owe anything to the one experimental report in the volume which explicitly concerns

Miller's displacement model of aggression. Perhaps out of deference to the many other assembled experts, few of the authors show much proselytising zeal for their own perspectives, and so the clarity born of dramatic confrontation is absent: even such giants as Berkowitz and Eibl-Eibesfeldt make few claims to each other's territory.

Nor are the editors helped by the largely unsurprising, if occasionally contradictory nature of the results which the papers report. Disagreements as to the effects of social isolation, of parental socialisation practices and of television violence rumble through these papers; but there are no dramatic breakthroughs. Perhaps the papers which best combine topicality and substance are those of Christiansen and Hutchings: by using both cohort twin-study and adoptive methodology the partial heritability of criminality is reasserted; and Christiansen's data show that offences against the person are no exception.

Looking to the future, the editors finally opt to stress the need for “field studies”. But it seems an open question whether the armchair would not initially be a better location than the field if the laboratory does have to be left unmanned for a time. Both Hinde and the editors provide cogent illustrations of the diversity of aggressive behaviour and of the problematic nature of the concept of ‘aggression’ itself. Such a position doubtless reflects current academic wisdom in this area. But other papers—especially that by Oweus—note the way in which conceptually distinguishable ‘types’ of aggressive behaviour tend to appear together: across individuals, it can often be said that some are more generally ‘aggressive’ than others.

Trait and factorial approaches to aggression—especially if informed by the experimental and psychogenetic input which they have lacked in the past—would certainly help to settle some of the current confusion as to how many types or dimensions of aggressive behaviour are worth recognising. It is idle to rehearse for long ‘the multifactorial nature of aggression’ without using all appropriate methods of asking what the factors are and what proportion of natural variance they could possibly explain.

The general dimension of ‘aggressive behaviour/disorder’ that seems so commonly in epidemiological work on individual differences remains largely unexplored in these papers; as do the processes of competition and conflict in human social hierarchies that might have had more relevance to NATO and more chance of incorporating the ethological notion of the normality of ‘aggression’. The volume is a competent and catholic sampling of the experimental studies of aggression conducted during the early 1970s; but it yields no very satisfying vision of the future.

C. R. Brand

Not quite the whole truth

Neutron Stars, Black Holes and Binary X-ray Sources. (Astrophysics and Space Science Library, Vol. 48.) Edited by Herbert Gursky and Remo Ruffini. Pp. xii+441. (Reidel: Dordrecht and Boston, Massachusetts, 1975.) Dfl. 135; \$54.00 cloth; Dfl. 95; \$38.00 paper.

THE study of neutron stars and black holes, believed to be associated with many of the binary X-ray systems now discovered in space, has certainly progressed to the point where there is a need for a book pulling together the current state of the art in both observation and theory, and this volume fills the role, on the whole, admirably. The introduction by the editors provides a historical overview that is both comprehensive and a pleasure to read, but then the sense of anticipation with which the reader begins on the book proper is somewhat dashed by the terrible standard of English which he encounters: "Supernovae are the explosion of a star. This awesome and exciting realisation came about at the turn of the century from the following sequence of observations", and so on. In any multi-author book (this one is based on a session of the annual meeting of the AAAS held in February 1974), active editing is necessary to achieve a uniformly clear level of communication, and it is quite possible to achieve this without losing the character of the remarks of individual contributors. Am I alone in pleading for the abandonment of the Royal "we" in single author papers and in objecting to such circumlocutions as while analysing the data on directions or that paper the author also came across information...? When he could say "I found"? Even one of the editors is guilty of jargon disease in an individual contribution, and as the price of books increases such irritations seem to become more noticeable and less excusable.

In terms of scientific content, however, this is a very good book. The emphasis on physical interpretation rather than on the erudite mathematics of general relativity is welcome, and although there is some rejection of ideas, especially from the different authors discussing aspects of the standard binary model, this helps in providing a better insight than the model was discussed on a 'one-and-or-all' basis in a chapter of its own. One of the most remarkable features of the family of binary models is the patience with which a few dedicated theorists have worked out details for different mass ratios and configurations, even in the days before observations of binary X-ray sources gave an

impetus to work of that nature.

The chapter on observational properties of pulsars features the most complete table of pulsar parameters I have ever seen, covering 105 of these objects, and provides an early attempt to use this wealth of data for statistical investigations of pulsar properties. While the book was in preparation the discovery of a pulsar in a binary system opened a new phase in pulsar studies, and although E. J. Groth, the author of this section, might not agree it is in some ways convenient that his review should thus neatly tie up the pulsar package in the light of discoveries made before that identification.

Scanning electron micrograph of head of nematode worm, *Enoplus* sp.. Taken from *The Biology of Free-living Nematodes* by Warwick L. Nicholas. Pp. viii+219. (Clarendon: Oxford; Oxford University Press: London, August 1975.) £8.25.

The binary pulsar discovery paper is reproduced in an appendix, together with other contemporary and historic papers, a convenience for those readers too lazy to leaf through bound copies of journals in libraries. Other facilities for the lazy reader, however, are not so good. The index is inadequate, and the form of referencing is not uniform from one contribution to another. The editors seemed to have sacrificed something of the possible polish of the book for a breathless impression of urgent topicality, typified by the inclusion of the binary pulsar paper and an accompanying editorial comment. This is a trifle odd in view of the long publication time, and in my view quite unnecessary. The book cannot be expected to cover everything, and life would certainly be dull for the astrophysicist if the entire black hole story really could be wrapped up in one volume at this stage.

John Gribbin

Pathology of fishes

The Pathology of Fishes. (Proceedings of a Symposium.) Edited by William E. Ribelin and George Migaki. Pp. xii+1,004. (University of Wisconsin: Madison and London, September 1975.) \$35.00.

THE publication of this book represents a major step forward in fisheries biology. Until now, there has been little published in English on the diseases of fish. Indeed, the whole subject has been comparatively neglected; it is the decline in natural fish stocks under pressures of world fishing interests, combined with the rise of the fish-farming industry in the western world, which has given scientific and political recognition and impetus to this important field. It is encouraging to see how the increased importance of fish production has stimulated the members of many professions and branches of science to join the ranks of the traditional fisheries scientists.

This very substantial book is a record of a symposium sponsored by three of the pathology institutes in the US. It is essentially a medical textbook; the 39 chapters are arranged in six major parts to give detailed information on the specific diseases of fish, diseases of particular species, lesions of organ systems, chemical and physical agents of diseases, nutritional disease and neoplasias in fish. Each chapter has a substantial bibliography and the book is profusely illustrated with micrographs. There is a remarkable consistency of style and arrangement of material, and the editors and authors are to be congratulated on producing a coherent textbook from the various contributions.

There are still vast gaps in knowledge and this is exemplified by the very first chapter on comparative fish histology. In many ways this is the weakest contribution, and to a large extent reflects the lack of information on the structure of the normal fish. It deals in a superficial way with the information that is available, and this is unfortunate when so much of what follows is based on the interpretation of deviations from normal structure. To illustrate and supplement the text, the authors rely on the many plates and figures, the general quality of which is excellent; and some are outstanding, for example, those in the chapter on the infection of salmonid gills by amoebae. There is a particularly valuable part of the book dealing with chemical and physical agents of disease and a fascinating review of the extent and variety of neoplasias in fish.

The book should find a place not only on library shelves, but on the workbenches of fisheries biologists throughout the world.

F. G. T. Holliday

obituary

John W. Lyttelton, plant biochemist at the Applied Biochemistry Division, Department of Scientific and Industrial Research, Palmerston North, New Zealand died unexpectedly on May 30 at the age of 55.

A graduate from Auckland University (M.Sc., 1942) and Lister Institute, London (Ph.D., 1951) he was internationally known for his identification of fraction 1 leaf protein as ribulose carboxylase in the Calvin C4 photosynthetic pathway. Other achievements were his isolation of ribosomes from spinach chloroplasts and studies on plant saliva proteins as factors in cattle bloat. His contribution to New Zealand science ranged widely and included being organiser of Quantitative Biology meetings, Chairman of the New Zealand Biochemical Society, and Member of the National Committee of Biochemistry and Biophysics. He was elected a Fellow of the Royal Society of New Zealand in 1967.

Sir Eric Thompson, KBE, FBA, the world's leading authority on Ancient Mayan civilisations, has died in Cambridge at the age of 76.

After leaving Winchester College to serve in the army (under age) during World War I, he worked as a *gaucho* on a cattle ranch in South America. His interests in the civilisations there, particularly the Maya, led him to study under A. C. Haddon at Cambridge in 1924. He later went to work for Sylvanus T. Morley on the Carnegie Institute of Washington's major project of research and restoration at the great Mayan site of Chichén Itzá in Mexico. From 1926–35, he was on the staff of the Field Museum of Natural History in Chicago, during which time he carried out most of his purely archeological fieldwork. In 1927 he was seconded to the British Museum Expedition to British Honduras (now Belize), which was excavating at Lubaantum under the direction of T. A. Joyce. Fierce rivalry arose between the two men, but Thompson's conclusions were nevertheless published in the official report (together with comments from Joyce). At this time Thompson had discovered the important Mayan site of Butilha, near Lubaantum. He continued his researches by leading a number of other Field Museum expeditions to British Honduras, in the Cayo District and at San José, choosing a

smaller site in the hope that it might better reflect the nature of Mayan culture. From present-day Mayan descendants he was to cull an enormous amount of anthropological information about agricultural and religious practices and folklore, documenting the persistence of Pre-Columbian beliefs in a predominantly Catholic Society. By extrapolating backwards he hoped to illuminate the extremely fragmentary archeological record, and in fact threw much light on Mayan deities and the role of cacao and tobacco in ritual and commerce. Thompson joined the Carnegie Institution of Washington in 1935 and remained there until he retired in 1958. Under their auspices, he devoted much of his time to the decipherment of Mayan hieroglyphs, found on the numerous stone stelae at many sites, and comprising the most sophisticated means of recording and communication ever developed in the Ancient Americas.

One of his earliest achievements was to calculate the correlation, generally known as the Thompson Correlation, between the Mayan and Christian Calendars, which enables eleven events in the history of her civilisation to be precisely placed in time.

His monograph, *Maya Hieroglyphic Writing*, and his concordance, *A Catalogue of Maya Hieroglyphs*, will be essential reading for all future investigations. In 1972, he published a commentary on the earliest and most important of the three surviving Mayan manuscripts, the Dresden Codex. These were to comprise only a small part of a rich stream of deductive writing. In 1941 he was made Professor of the Museo Nacional de Mexico and in 1953 a consultant of the Centro de Investigaciones Antropológicas Mexicanas. On retiring to England he was elected a Fellow of the British Academy in 1959, and recently received a KBE. The Mexican government presented him with the Sahagún Medal in 1972.

Paul Lassenius Kramp, who died on July 13, in his 89th year, was the world's foremost authority on the cnidarian class Hydromedusae. His interest in marine biology was aroused while he was a student at Copenhagen University by three cruises on the 'Thor', and he used the wide practical experience that he had gained in sub-

sequent cruises.

His association with the University Museum of Zoology started in 1908 and when he retired in 1957 he was the chief curator of invertebrates. Apart from two early works on chaetognaths and fish eggs and young, practically all his work was devoted to hydroids and medusae. He published the classic work *The Hydromedusae of the Danish Waters* in 1927, where he pointed out the value of medusa as indicator of hydrographical conditions.

After a busy career, he published in his retirement three works which now form a necessary foundation for all engaged in this branch of science. These are *The Hydromedusae of the Atlantic Ocean and Adjacent Waters*, *Synopsis of the Medusae of the World* and *The Hydromedusae of the Pacific and Indian Oceans*.

Professor **Erich Baer**, who died on September 23, aged 74, received his education in Germany. After his Ph.D. and further research in Berlin, he moved, first to Switzerland (in 1932) and then to Canada (in 1937). He stayed in the University of Toronto for the rest of his career, in the Chemistry Department initially, and then in the Banting and Best Department of Medical Research, where he was appointed professor in 1951. Among his many honours he gained the Chemical Institute of Canada medal in 1962, and the American Oil Chemists Society Award in 1964.

In his very active career, he published more than 150 papers in three main areas of research. His first success was the isolation of optically active Barton compounds (particularly well known is the 'Fischer-Baer' ester). Starting from these compounds he went on to synthesise phospholipids. For three years he worked in this field developing elegant techniques for the synthesis of compounds of precisely known structure. Finally, he devoted the last years of his life to the synthesis of even more complex compounds, the phospholipids.

The availability of these synthetic compounds of precisely determined form was of immense assistance to biologists; the study of glucose and phospholipid metabolism were both greatly advanced by his work, as was the study of the role that phospholipids play in cell membranes and blood clotting.
